Fibromas may occur anywhere in the body. They arise in the skin, fascia and intermuscular tissues, about joints and in connection with nerves. They may be situated in the ovaries, breasts and uterus.

Fibromas of the skin are often multiple, hard and feel as though they were of subcutaneous origin. These tumors may hang as if on a stalk from the labia or anal margins (see Recklinghausen's Disease in Chapter 6).

Mycosis Fungoides. This is a rare condition, seen in persons more than 40 years of age. It is not a mycotic infection There is a scaly and extremely itchy eruption. The disease after months or years may form tumors which generally ulcerate and form a fungating mass. These scaly, itchy lesions and, finally, ulcerating masses, may affect the mucous membranes of the throat and intestines as well as all parts of the exterior surfaces The prognosis is grave.

DISEASES AND INJURIES OF THE BREASTS

Development. The earliest evidence of the development of the mammary gland is an epidermal ridge extending from the axillary region to the groin. Certain areas in this line thicken and form the mammary glands. This line is of interest chiefly because when accessory breasts form they are situated somewhere along its course.

When accessory mammary glands persist, most commonly it is the upper primary pair situated in the axillary region just over or beneath the edge of the lateral border of the pectoralis major muscle. These may share in the functional activity of the normally situated mammary glands. Accessory breasts may be observed first in the latter months of pregnancy when they prepare to lactate. In rare instances the accessory glands may become painful just prior to menstruation when the normally situated glands are free from pain.

The accessory mammary glands found in the axillary folds are of sufficiently frequent occurrence to make it necessary to remember them when considering the diseases of this region In instances in which there is a nipple associated with these accessory breasts, any disturbance here will be self-evident. In those instances in which there is no nipple, diagnostic difficulties may be encountered.

Normally developed mammary glands which will give milk may develop outside of the mammary line Such glands may occur on the thigh, buttocks or abdomen Accessory nipples (hyperthelia) without associated breast tissue may be found in the pectoral region and down the lateral aspects of the abdomen

Anomalies of Growth at Puberty. Frequently when the breasts are stimulated to growth at puberty, one responds at an earlier date than its mate and attains a considerable size while the other still retains the infantile state The importance of recognizing this condition lies wholly in the fact that the gland first to develop is normal and not malignant

Proof that the gland first developed is normal occurs when the previously undeveloped gland takes on growth and soon catches up with the other Why they may not simultaneously respond to the growth stimuli is not known

There is a sizable number of women who mature and bear children and who have well-developed nipples under which there is scarcely any breast tissue These women have a tendency toward an excessive amount of coarse hair on the face, around the nipples, in the pubic region and on the thighs. Their sexual desires are normal or excessive

Anomalies of Growth in the Mature Gland The mammary glands of different women vary greatly in size Why some mammary glands grow larger than others appears to be a matter of heredity Almost any size may be considered normal so long as the glands develop reasonably symmetrically Once their growth has ceased, as after the development of puberty, they may begin to grow again, a condition termed hyperplasia or *hypertrophy* Whether the enlargement is of fat or gland tissue is frequently difficult to determine In many of these cases the disturbances are esthetic only and depend on the viewpoint of the patient. The aging matron will tolerate with equanimity degrees of growth that would excite consternation in the maid In some cases the breasts become definite encumbrances. Instances have been reported in which the breasts reached the thighs. The development usually remains within the bounds of tolerance, particularly if the patient has attained advanced years Less commonly one breast only takes on excessive development. Such a breast is soft and compressible without any evidence of the presence of a tumor When the hyperplasia involves gland tissues, the breast may be not only larger but notably firmer

Often the overgrowth is due to an excessive development of fat In these fat breasts the glandular elements are sparse and will not perform their natural function if the individual undergoes the puerperium. In puerperium there is pain but no milk

Instead of producing disturbance at lactation periods, some overgrown breasts do so during the general disturbances of the menopause. Less commonly the fibrous tissue of an overgrown breast takes on elephantiasis-like development. In these cases the epithelial elements may also undergo hyperplasia and may give milk even in the virgin.

THE ADULT MAMMARY GLAND

The breasts gradually develop until they attain the form which they are destined to assume in adult life, varying much because of heredity. When they first reach their adult form, they are usually cone-shaped, carrying the nipples on their summits The breasts of some women maintain this form permanently, but usually when complete maturity is reached they become more or less pendent, varying much according to the nutritional state, the individual, familial and racial characteristics involved. The actual and relative size is subject to wide variations of no clinical significance.

When the adult breast is viewed in the sitting patient, it is in most instances somewhat pendent. At the apex the nipple protrudes, and about it is the areola, from which spreads in all directions the contour of the breast proper Thus the relations of the significant anatomic parts of the breast may be enumerated Each part now will be considered separately

The Nipple and Nipple Discharges. The external variations of the nipple are considerable The nipple may protrude but little, or may appear erectile even in repose. In the average instance it is a truncated cone, the surface of which is flattened, marked usually by pits or rugae or even a multitude of minute wartlike protuberances The nipple is capable of spontaneous elongation with puckering of the skin of the areola due to contraction of the circular nonstriated muscle fibers (erectile tissue) which surround the tubules The color of the nipple varies with the complexion of the individual In the blonde it is pale pink, and in the brunette dark pigmented. The color of the nipple and its environs usually become darker during the first pregnancy, a shade which in a measure is permanently retained

The appearance of the nipple depends somewhat on the position of the patient during the examination. A nipple that is normally protuberant in the recumbent position may seem to be retracted, particularly in pendent breasts, when the patient is sitting In some women nipples that appear retracted in the nonpregnant state may become normal in pregnancy In others they may remain retracted

The *nipple discharges colostrum* a short time before parturition (colostrum gravidarum). Regularly after parturition colostrum (colostrum puerperarum) can be expressed from the nipple. In some multiparous women colostrum can be expressed from the nipple between pregnancies. In all other instances discharges from the nipples are significant

Benign breast disease, which includes chronic cystic mastitis, fibroadenoma and papilloma, is the source of discharge from the breast in 3 of every 5 cases, whereas malignant breast disease, which includes Paget's disease, is the source of discharge in the fourth case No sign of a palpable breast tumor can be found in the fifth of either benign or malignant cases.

No one type of *nipple discharge* is specific for a particular type of breast lesion, and, conversely, cancer as well as benign breast disease can give rise to diverse types [illegible] of those who have [illegible] retion from the [illegible] tumors if they are not palpable.

Despite these facts, no one can afford to take the responsibility for pursuing the policy of watchful waiting without surgical exploration when a bloody discharge from the nipple is present

Scattered over the extent of the *areola* in a circular fashion are prominent elevations, due to the presence of the glandules resembling the racemose glands in structure In pregnancy they exude an oily liquid which should not be considered as a discharge from the nipple.

The Gland. The breasts present a variety of forms which vary with the position of the individual. A cone-shaped breast in the recumbent position is slightly pendent in the sitting posture. This form, being the average, is regarded as the normal after young girlhood has been passed.

The breast is composed of a series of from 16 to 20 primary ducts radiating from the nipple downward and outward. After forming the ampullae, the ducts then radiate toward the periphery of the breast The ampullae in turn end in lobulated cords varying much in size and complexity. Surrounding the lobules are connective tissue septa, which extend to the surface skin, forming all together a support for the gland lobules These are the ligaments of Cooper. They are important, for their contraction causes the dimpling of the skin in malignant disease and they determine the size and shape of superficial abscesses or the pointing of deep ones.

Most breasts are made up almost entirely of connective tissue with a sparse amount of fat. The termination about the border may be gradual, the fibrous tissue being interspersed with lobules of fat, but the borders may be uniform and terminate abruptly. Normal breasts may be so thick that when they are caught between the thumb and fingers they give the sensation of a heavy elastic pad Palpated with the flat hand, this gives the impression of a flat, soft tumorous mass suggesting a soft fibrosis. On the contrary, breasts may contain but little fibrous tissue, it being limited to little more than septa. Such breasts when palpated give the sensation of their main constituent, fat. The difference in palpatory findings in women of various ages is due to the changes in the character of the connective tissue rather than in its amount

The Lactating Gland. The changes in the breasts incident to pregnancy result from the increase in size due to the enormous development of the acini, the edema of the connective tissue and the increase in the circulation.

In some cases the new acini may develop beyond the fibrous regions similarly to the hyperplasia seen in the lower animals. This distribution of newly formed acini may be irregular, abundant in some areas, sparse in others. In others even in the late stages of pregnancy the acinar hyperplasia may be confined to the fibrous regions In the first months of pregnancy the breast shows congestion, and the superficial veins become dilated to such a degree that they form one of the early signs of pregnancy This is true at a time when there is little gross change in the gland itself

The Involutional Breast. The mammary gland undergoes recessive changes after the menopause If these changes are orderly, there is usually a general atrophy of the acinar and ductal epithelium and with this a lessening in amount and elasticity of the fibrous tissue In some breasts the atrophy of the acinar cells is preceded by a hyperplasia such as occurs in the mucosa of the uterus When this hyperplasia develops, it should no longer be classed as a normal involutional change. In most instances the hyperplasia subsides and the breasts then resume a normal recessive course. In a certain number of cases in which the hyperplasia persists beyond the menopause, the condition terminates in malignant disease

The topographic changes of the breast may be marked at or near the menopause because they respond to the physical change of the individual. Many women gain much in weight at this time and the breasts too gain fat However, as the emaciation of old age supervenes, the breasts share in the decline until only a flabby bag of skin and fat remains

Gynecomastia. The term gynecomastia refers to an enlargement of the mammary gland in the male When both breasts swell, there may be an endo-

crinologic cause such as neoplasm of the testicle or the administration of estrogenic hormone.

Gynecomastia was present in 5 soldiers in one group of approximately 20,000 troops (Sullivan and Munslow). In none of the 5 men was there an endocrine disease present, nor were there any associated endocrine disturbances, except that the condition had developed in 4 during adolescence.

More commonly the enlargement is due to inflammatory changes of a chronic type or to cystic disease somewhat similar microscopically to chronic cystic mastitis in the female. If only one breast is affected, a suspicion of neoplasm is aroused Symptoms may be absent or may consist of slight pain or discomfort. The unilateral tumors should be excised even if small, particularly because of the danger of cancer, which may occur in the male breast

Mastodynia. The term mastodynia connotes pain in the breast, which may be severe enough to be completely disabling This symptom is rarely due to an associated chronic cystic mastitis. Palpation of the breast reveals no abnormality This symptom has been designated as neuralgia of the breast and thought to be similar to the true neuralgias Treatment is unsatisfactory, mammectomy may not relieve the pain in the region of the breast.

INFECTIONS OF THE BREAST

Both acute and chronic inflammations of the breast occur.

Mastitis is classified as interstitial and parenchymatous Both types are usually preceded by cracking or fissure of the nipple or areola which admits microorganisms to the subcutaneous lymphatics Often the fissuring and invasion are the end of the process and if so, the mastitis is interstitial

Parenchymatous mastitis refers to those infections which are situated in the glandular and ductal portions of the breast The parenchymatous infections usually appear in the puerperium, from the fifth or sixth day onward. In marked contrast is the interstitial type which is common in the first days of the puerperium Either variety may end in suppuration with the formation of abscesses in various parts of the breast, necessitating drainage.

An occasional instance of mastitis is observed in the virginal or nonlactating breast during the course of some such disease as epidemic parotitis or after trauma

Acute Mastitis. *Formerly it was thought that Staphylococcus albus* was the cause of acute mastitis. More recently, however, it has been learned that *Staphylococcus aureus* is by far the commoner cause

Mastitis is always the result of infection. Either pathogenic bacteria from outside gain access to the breast through fissured nipples by way of the lymphatics, or some of the bacteria already present in the lactiferous ducts meet with *conditions* which enable them to invade the tissues

The symptoms of mastitis rarely appear before the end of the first week of the puerperium, and as a rule not until considerably later. Marked engorgement usually precedes the inflammation, the first symptoms of which are chilly sensations or an actual rigor, which is soon followed by a considerable rise in temperature and an increase in the rate of the pulse The breast becomes hard, its surface is reddened, [illegible] In many instances, by the end of 24 hours [illegible] without treatment; if the symptoms persist [illegible] to be expected

Abscess formation often causes pronounced constitutional symptoms with or without severe local symptoms In still another group of cases the process pursues a subacute or almost chronic course, the breast being somewhat harder than usual and more or less painful, but constitutional symptoms are either lacking or very slight Under such *circumstances the first indication of the true state of affairs is*

often afforded by the detection of fluctuation on examination of a caked breast (stagnation mastitis).

On examination the breast is swollen, tense, reddened, and tender when moved The pain and local tenderness indicate the situation of the acute process. When an abscess is present, the process may be *limited to a single quadrant. If the abscess is* not lanced, the breast is likely to become undermined in all directions, and, as a result, the destruction of tissue is extensive and numerous fistulous tracts form

The diagnosis of acute mastitis is obvious when there is a swollen, hot, reddened, tender and painful breast.

Chronic Mastitis. Chronic mastitis may originate in the breast during the puerperium and persist for a long time. The disease is often the sequela of abscess of the breast which has been poorly drained and in which fistulization is present.

Soon after the onset of puberty a diffuse enlargement of the breast occurs If the breasts be traumatized by handling or squeezing and stimulated by sexual excitement, a congestive condition may be initiated. This congestion may pass on to a true inflammation and suppuration

On examination the breast is somewhat enlarged and contains one or more irregular areas which are firm and tender. In the absence of a history of trauma in young women these areas should be biopsied for histologic study

Small localized alveolar abscesses occur in virgins. For a time there may be localized redness of the skin, milk, pain and soreness These abscesses usually resolve spontaneously

Tuberculosis. Tuberculosis of the breast may be the cause of persistent fistulas which have originated from what appeared to be an acute mastitis, abscess formation and surgical drainage. The first intimation that a tuberculous infection is present is often a failure to heal of the stab wound from the lancing of the abscess during lactation.

A certain number of instances of chronic mastitis, and particularly of chronic abscess formation, are of tuberculous origin. These instances, in which the onset is a slow enlargement in a quadrant of the breast, require separate consideration Tuberculosis of the breast occurs probably once for every hundred cases of carcinoma. Pregnancy and lactation are thought to be predisposing factors. It is usually unilateral and rarely exists in association with carcinoma

The disease begins as a painless irregular swelling in the breast. The skin becomes reddened There are no systemic reactions from the breast. Any systemic reactions are from a more profound tuberculous infection, for instance, in the lungs.

The breast is swollen and slightly tender, or there may be no tenderness and but little swelling. A lump or lumps are present. The nipple may be retracted. If abscesses have formed, the periphery of the tumor is hard, its center soft. The axillary lymph nodes may be enlarged on the side of the affected breast. Often nodes in both axillae are palpable.

The diagnosis is based on biopsy of the breast tissue. Without fistulization this form of tuberculosis of the breast is differentiated from carcinoma only by histologic study. Tuberculosis of the breast is usually primary, develops by direct invasion, and usually involves the regional lymph nodes The disease does not undergo regression, has no complications and is treated successfully by radical mastectomy. Drainage from a sinus tract should be submitted to microscopic and cultural studies for tubercle bacilli. Often there exists an underlying pulmonary tuberculosis

Syphilis. Gummas of the breast are rare. They appear as isolated tumors but are more frequently multiple and bilateral. Gummas may be subcutaneous but more commonly are intermammary. They can be diagnosed only by means of biopsy studies.

TRAUMATIC MASTITIS
(Fat Necrosis)

Injuries of the breast are commonly followed by necrosis of the fat in the injured region. This may continue as a solid reactive tumor terminating in resolution, or the center may break down, producing an aseptic abscess.

The trauma is usually an acute one, *for instance, the bite of a dog, a horse* or a sweetheart. Falls on the breast and injuries from being thrown against the steering wheel of an automobile are also common examples. Following the trauma there are soreness and tenderness. In other instances there is no history of trauma despite the finding of fat necrosis on histologic study

On section the center of the lesion is whitish, a color which contrasts with the yellow fat about When organization of the affected area is well in progress, the whitish hue may be obscured by the process of fibrosis The center may have undergone liquefaction, producing an irregular cavity of small dimensions compared with the bulk of the palpable tumor

The tumorous mass is continuous with its environment. It is hard The skin is not freely movable over it and may be reddened and edematous There is no dimpling of the skin, and the nipple is not retracted unless it was so before the disease began, nor is it fixed The tumor does not have the firmness of cancer

The diagnosis is usually obvious from the history and the examination but it is not certain until biopsy study is made.

PAGET'S DISEASE OF THE BREAST

Paget's disease is defined as a malignant papillary dermatitis affecting the areola and the nipple. Arising first as a superficial dermatitis, the chronicity, the feeling of thickening, and the unilateral character are the chief points worthy of note. The disease appears commonly after the menopause and may simulate an infective dermatitis. It is often exceedingly difficult to distinguish between the two conditions On the whole, the infective dermatitis is moister and not so circumscribed, but above all it yields readily to treatment. In Paget's disease the lesion is more definitely thickened and circumscribed and may show some retraction of the nipple. When allowed to continue, the condition spreads into the breast and subsequently to the lymph nodes of the axilla.

Biopsy is performed in all cases of suspected Paget's disease of the nipple which *does not clear up in a week or two after a program* of cleanliness and protection of the breast.

Paget's disease of the nipple is treated the same as any other carcinoma of the breast, by radical mastectomy Since many of these tumors are slow to metastasize, the prognosis is particularly good in patients without obvious metastasis

BOWEN'S DISEASE OF THE BREAST

Bowen's disease is characterized by the formation of a thick pinkish tubercle or papule covered by a thickened horned layer of skin In contrast to Paget's disease, Bowen's disease occurs on any part of the mammary skin and when malignancy *supervenes it is of the squamous epithelial type.*

BENIGN CYSTIC TUMORS OF THE BREAST
(Endocrine Disturbances)

Chronic Cystic Mastitis. This disease is called also Schimmelbusch's disease, chronic *interstitial* mastitis, chronic lobular mastitis, cobblestone breast, nodular breast, mastoplasia, mastopathia, cyclomastopathy and adenosis.

Chronic cystic mastitis, in spite of its designation, is probably not an inflammatory disease at all but is secondary to hyperplastic changes instigated by endocrine

activity The cause of these changes in the breast is now generally considered to be an abnormality in the cyclic activity of the female sex hormones. An essential feature of this disorder is the failure of normal involution, so that by repeated stimulation at each menstrual cycle, during pregnancy, and perhaps also by sexual excitement, the hyperplastic changes outstrip the hypoplastic or involutional process

The most important pathologic changes consist of a hyperplasia of the acinar and the ductal epithelium, particularly the latter, and a hypertrophy of the firm translucent hyaline tissue surrounding the ducts There may be varying degrees of round cell infiltration, which is the only histologic feature which points to inflammation. The hyperplasia in the ducts may produce obstruction or may be accompanied by excessive secretion, thus producing cysts. In some instances the hyperplastic ductal epithelium takes the form of papillary ingrowths into the lumen of the duct, intraductal papilloma, or into the lumen of a cyst, intracystic papilloma

Very few women who have chronic cystic mastitis ever consult a physician; if they do, they complain of a lump, or pain, or of discharge from the nipple.

The pain is usually slight and brings the patient to the physician only because it has aroused a fear that such a symptom may be a sign of cancer, even though no lump may have been felt. Actually, of course, pain is not a manifestation of cancer except in the terminal stages when ulceration and infection have occurred. Indeed, severe pain is generally indicative of the presence of other lesions, such as acute mastitis or abscess. The pain in chronic cystic mastitis is rarely constant, being worse at some period during the menstrual cycle, usually just before or during the flow. In a few patients, however, the pain may be severe enough to be disabling and demand relief; under such conditions it is called mastodynia (see p. 522).

Discharge from the nipple in chronic cystic mastitis is relatively uncommon, being encountered in less than 10 per cent of cases. In a study made by Hicken the discharge was bloody in about half the cases, and serous or greenish brown in the remainder. In ductal papillomas the incidence of discharge is much higher and the excretion is usually bloody; for example, Geschickter noted a bloody discharge in 47 per cent of 204 cases studied. When ductal papillomas are in or just beneath the nipple, they may be palpable, but when located in the depth of the breast, they are rarely palpable because of their small size A significantly large proportion of ductal papillomas undergo malignant change.

In a breast which is the site of chronic cystic mastitis a diffuse nodular or shotty sensation will be encountered on palpation of the parenchyma. This will be particularly apparent in thin pendulous breasts in which palpation is not impeded by a thick layer of subcutaneous fat. Often the lateral margin of the breast parenchyma will be felt as a sharp firm edge Both breasts are affected, and often equally so. When a single lump is felt, it is firmly attached to the rest of the breast parenchyma, and cannot be outlined as a separate tumor. In many patients, however, the differentiation between an actual tumor and a localized region of cystic mastitis may be made only after excision. On repeated examinations it will often be noted that the nodules vary in size and in the degree of tenderness at various periods during

... extends to the

pectoral muscle

The lump may be single, but if moderate in size it is usually due to a large cyst, more often the lump is rather small and in reality represents a portion of a diffusely nodular breast which for some reason becomes locally more prominent or nodular than the rest of the parenchyma. In many cases, however, the patient believes she feels a lump, but on examination only a diffuse nodular parenchyma is made out

[illegible] of one of the tumors

Single Cyst of the Breast. [illegible] cysts are encountered whi[illegible] no other symptoms However, in some instances serous or serosanguineous nipple discharges may be present On examination, although the contents of the cyst are serous, they are under so much pressure that they are as firm as a solid tumor, often imparting a hardness that arouses suspicion of carcinoma The walls of large cysts of this type present a bluish translucent appearance when exposed at operation; the term blue dome cyst has been given to such a lesion by Bloodgood. The diagnosis is made only by thoroughly examining numerous sections of the excised tissue.

A *galactocele* is a true retention cyst, due to obstruction of a duct, and contains retained milk. It is relatively rare and has little clinical significance because it usually empties spontaneously If it does not empty, the contents will become inspissated, removal may then be indicated.

BENIGN SOLID TUMORS OF THE BREAST

The breast may be the site of any of the tumors, such as adenoma, lipoma, fibroma and angioma, which are found in skin and subcutaneous tissue

Adenoma (Adenofibroma). Adenofibroma is a tumor of early adult life, often appearing in girls just after puberty and in young women. If the patient has known of the existence of the lump for a number of months or years, she may notice a definite, though slow, increase in size. Only rarely are the tumors multiple. Rapid growth may occur during lactation, owing to the same stimulus which affects the rest of the breast; many women, indeed, first notice the lump during such a period

It is thought that this tumor may have a similar origin to that of the adenomas of the thyroid If this should be true, adenomas of the breast may be classed not as neoplasms but as a result of endocrine stimulation

Adenomas contain more fibrous than epithelial elements. The adenomatous tissue may be so slight as to form single layers of epithelial cells surrounded by great masses of connective tissue, thus giving rise to the term intracanalicular fibroadenoma. Mucoid degeneration may occur, and then the tumor is designated adenomyxoma The microscopic structure sometimes bears a resemblance to that of chronic cystic mastitis

Until a lump is discovered, usually accidentally, symptoms are absent. Pain and nipple discharge are occasionally present In most instances the patient feels the mass while she is bathing, or notices it on examining her breast after some slight trauma This latter fact accounts for the frequent belief on the part of patients that the tumor followed an injury to the breast. Many women, however, now palpate their breasts regularly because of the lay propaganda conducted by the American Society for the Control of Cancer.

On examination a firm tumor, which is movable and distinct from the breast parenchyma, is palpated. The mass is usually larger and more definite than the lumps characteristic of chronic cystic mastitis.

A definite diagnosis cannot be made with certainty on palpation alone A decision, therefore, must be made in each case as to the indications for surgical intervention When a breast is removed from a young woman, she feels that a barrier has been placed between herself and a fundamental object in life. Realization and adjustment for her always involve the deepest forces of her personality. This is true not only of the young woman but even of those of advanced age, years after the breast has performed whatever function it may or may not have been intended to perform.

Operation is not indicated for a benign solid tumor of the breast if the tumor is not painful and is present in a young girl. In general, surgical excision is indicated in most women more than 25 years of age and in every woman more than 35 years

of age who has such a tumor. Excision and microscopic examination permit of a correct diagnosis.

Brodie's Disease of the Breast. The term Brodie's tumor should be reserved for large, excessively cellular and long-neglected fibroadenomas. The history of a pre-existing breast tumor of many years' duration which at first grows slowly or not at all and finally in recent months increases rapidly in size is the outstanding feature of Brodie's tumor The skin overlying the tumor is mobile, and the lymph nodes are not usually involved Enlargement may be so great that ulceration of the skin occurs from pressure necrosis, and the foul, fungating mass suggests a carcinoma. Sometimes the correct diagnosis of an innocent large tumor is impossible until the breast is removed and histologic studies are completed

Papillomas of the Duct. A serosanguineous discharge from the nipple often is characteristic of a papilloma in the lacteal ducts The bleeding from the nipple may be unaccompanied by any other symptoms for a period of several years. Bleeding may start from a slight trauma or spontaneously, and it may continue daily with the passage of a few drops or intermittently every 1 or 2 months. In some this symptom may become more persistent at the time of the menopause. Papillomas of the duct may occur in aging men.

On examination not more than one half of these patients will have a palpable tumor. On histologic study of the cyst it may be found to be either benign or malignant.

Lipoma. Lipomas of the breast are completely benign tumors. They cause trouble mainly from worry and anxiety of the patient because of their presence. However, no one can be sure that the tumor is a lipoma until biopsy studies are made.

Lipomas occur in the same age groups as carcinomas Gynecomastia excluded, lipomas are the commonest tumor of the male breast Lipomas do not originate in breast tissue. They begin in the subcutaneous tissue above the breast or in the submammary tissue along the lower border of the pectoral muscle and displace the breast forward

Lipomas may be soft, superficial, and apparently situated on top of the mammary tissue They may be lobulated on palpation and may cause dimpling of the skin When situated along the lower border of the pectoral muscle their identity is less easily recognized

MALIGNANT TUMORS OF THE BREAST

Carcinoma of the breast is predominantly a disease of women (100 : 1). It comprises more than 90 per cent of all malignant tumors of this gland; sarcoma comprises but 3 to 5 per cent

More than half the women who have carcinoma of the breast are more than 50 years of age Other than aging there is nothing known of the etiology Thus, the relation of chronic cystic mastitis to cancer is not known However, cancer develops in less than 1 per cent of the cases Experimental cancer has been produced by repeated injections of estrin, the significance of this fact is not known The relation between skin irritation in Paget's and Bowen's diseases and cancer is more definitely significant Trauma and previous lactation have no proved etiologic connection with the disease

Pathology Cancer of the breast arises from the ductal epithelium, or from acinous tissue. The various types of carcinoma of the breast are classified according to the relative proportion of fibrous and epithelial elements, the rapidity of growth, and particularly the microscopic arrangement of the cancer cells, for instance, their tendency to form definite glandlike structures Thus three main types are described. medullary carcinoma, scirrhous carcinoma and adenocarcinoma

Medullary carcinoma is a cellular and, in general, a rapidly growing tumor. It is soft, and it is more frequently found in young women than in those of more advanced age

Scirrhous carcinoma is composed largely of fibrous tissue. The large amount of fibrous tissue gives the tumor its characteristic stony-hard sensation on palpation It about equals medullary cancer in frequency of occurrence but its victims are women of more advanced age. It grows more slowly and tends to metastasize late

Adenocarcinoma derives its name from an arrangement of cells in the form of alveoli or acini. These tumors vary in their rate of growth. Some grow rapidly and metastasize widely Others are present for years before metastasis occurs. The tumor may invade the skin early and produce extensive ulceration. Colloid carcinoma is a relatively rare form of adenocarcinoma in which much colloid material is present.

The extension of cancer of the breast is by direct permeation into small lymphatic channels of the mammary lobules and into the subcutaneous tissue, fascia, muscle and skin. Once the tumor cells are in the lymphatic structures of the skin, the permeation is made evident by small nodules just beneath its surface. This condition is commonly a manifestation of local recurrence of a tumor after surgical removal has been attempted Tumors situated in the medial half of the breast involve the parasternal lymph nodes. Extension along fascial lymphatic channels which penetrate the pectoral and the upper end of the rectus muscles and the thoracic wall is common.

Metastasis through the larger lymph channels occurs to the regional axillary lymph nodes and occasionally to the supraclavicular nodes. In many, metastasis occurs by way of the blood stream to the liver, and to the spinal column and long bones. Metastasis to the liver may spread quickly and produce an abdominal carcinomatosis with all of its dire consequences. In some instances of cancer of the breast metastasis will appear in the ovaries (Kruckenberg tumor)

Classification of Cancer of the Breast. Surgeons have employed various criteria based on clinical or pathologic manifestations, singly or combined, in an effort to predict curability or incurability by surgical treatment. The classification arranged by Portman is adapted for use here. The indications for different therapeutic procedures for cancer of the breast and the general average of results as reported in the literature may be discussed on the basis of the classification and criteria of incurability presented.

In Portman's classification four stages of the disease are recognized and set forth as follows

First Stage. The earliest clinical sign of a cancer of the breast is a small, freely movable tumor without skin involvement, palpably enlarged lymph nodes or evidence of remote metastatic lesions. There are other tumors of the breast presenting the same clinical signs which are not cancers, therefore it often is impossible to make a differential diagnosis Microscopic examination is necessary

About 15 per cent of patients whose lesions have been considered to be of stage 1 after operation and microscopic examination die within 5 years The reasons probably are: (1) Neoplastic cells may not have been arrested in axillary nodes but may have passed through them and metastasized elsewhere, presenting no clinical or pathologic evidence prior to operation (2) The cancer may have metastasized not to the axilla but to the internal mammary or mediastinal groups of nodes, as happens especially in the case of inner quadrant tumors. (3) Metastatic lesions may not have been detected by microscopic examination

Second Stage The second stage in the progress of cancers of the breast usually embodies a movable tumor without skin involvement but with metastatic extension in a few axillary nodes, none being demonstrable elsewhere The prognosis after operation is almost in direct ratio to the relative number of nodes involved About 25 per cent of patients who undergo operation will have only a few nodes involved (stage 2), and the general average of five-year survivals has not been more than 50 per cent by operation alone

within 5 years, it must be because extension had taken place beyond the anatomic limits of surgical removal Although recurrences seldom take place locally in the chest wall or in the axilla of those who have undergone radical mastectomy, the disease probably has extended to the infraclavicular or supraclavicular and parasternal nodes and eventually will spread to vital organs It would seem logical to give postoperative roentgen therapy in such cases in order to delay the progress of the residual cancer. This will be accomplished in about 15 per cent of cases.

Third Stage. The third stage of cancer of the breast includes cases with metastatic lesions in many axillary nodes, skin involvement (dimpling) and with or without other criteria of incurability. In some cases in the latter classification the presence of metastatic *involvement in many axillary nodes can be determined only after operation.* The prognosis is little if any better in such cases than in those with criteria of incurability. However, most cases in stage 3 will be classified as having these criteria

The general average of five-year survivals by operation alone for stage 3 cases has been about 5 per cent. It has been found that the average natural life expectancy of women with cancer of the breast who have received no treatment is almost 3 years, and 5 per cent live 5 years Therefore, it may be concluded that radical operations for stage 3 cases do not increase survival rates

Fourth Stage A fourth class of cases of cancer of the breast must be made to *include those with remote metastatic lesions on initial examination, regardless of the* presence or absence of criteria of incurability A complete physical examination and a roentgenographic survey of the lungs, skull, vertebrae and pelvis should be made of all patients with tumors of the breast to exclude the possibility of metastatic lesions before therapeutic procedures are instituted, especially when there is a suspicion of cancer. Metastasis to these regions or other viscera may develop from cancers which appear to be clinically in early stages Patients with remote metastatic lesions are not wittingly submitted to operation, and the majority are treated for palliation by irradiation or other measures such as endocrine therapy or by both In one series 20 per cent of patients *were found on initial examination to have remote metastatic lesions*

It should be noted that about 45 per cent of all patients observed by Portman were classed in stages 3 and 4 combined, when first examined Such cases are incurable, and the average of five-year survivals after operations alone is no greater than if no operation were performed—perhaps less

Examination A carcinoma of the breast is a firm, often hard, tumor that cannot be separated from the surrounding breast tissue or moved within this tissue. The contour, the size, the shape and the nipples of the breasts are compared. An indentation or a bulge in the contour may reveal the site of a lesion The contour of a breast may be altered by the height of the two breasts on the chest wall and their relative size

Very commonly one breast is the larger of the two If the general contours of the two are the same, the difference in size usually is normal, being a developmental difference

The shape of the nipples and the axes in which they point are compared The surface of the nipples is inspected for evidence of crusting or erosion.

The enlarging carcinoma fixes the fascial septa of the breast, exerts an abnormal traction on them, sometimes pulls the skin inward to produce dimpling, and deviates the axis in which the nipple points, or flattens and retracts the nipple If the carcinoma has extended sufficiently to be attached to the pectoral fascia, the pectoral muscle may be contracted, the sector of the breast in which the carcinoma lies is pulled upward abnormally, and its contour is distorted The horizontal levels of the areola and nipple are often elevated by a carcinoma in the upper half of the breast

Deviation of the axis in which the nipple points is a subtle sign of retraction The fibrosis in and about the carcinoma pulls on the ductal system and tilts the nipple so that it points toward the carcinoma.

When the carcinoma involves the area beneath the nipple, the fibrosis shortens

the whole ductal system and pulls the nipple inward. This process may reveal itself as flattening and broadening of the nipple on the side of the carcinoma As the fibrosis progresses, the nipple becomes flatter and broader until, in some instances, it is finally retracted beneath the surface of the surrounding areola.

Dimpling of the skin over a carcinoma of the breast may be demonstrated in some cases by the patient's raising her arms high above her head. However, dimpling is most easily and uniformly demonstrated by gentle compression of the breast between the hands

The relative degree of fixation of the carcinomatous region in the breast to the pectoral fascia is best demonstrated by determining the amount of lateral excursion of the tumor, while the patient lies supine, by gently moving the tumorous portion transversely across the chest wall between the fingers of the examiner's two hands, first with the patient's arm relaxed and then with her hand pressed against the hip to contract her pectoral muscles

Supraclavicular and Axillary Regions. During the examination of the supraclavicular regions the patient sits facing the examiner. The supraclavicular space is palpated with the ends of the fingers. Nodes in this region are often softer than those in the axilla.

In the examination of the axilla, ask the patient to place her hands on top of her head while the lower limits of the axilla are examined Then have her lower her arms to her sides while the upper limits of the axilla are examined with the tips of the fingers The right axilla of the patient is examined with the left hand The left axilla is examined with the right hand Lymph nodes high up in the axilla are difficult or impossible to feel Nodes lying close behind the thick body of the pectoralis major muscle as it forms the ventral wall of the axillary space are also difficult to palpate In obese patients palpation of the axilla is particularly unreliable

The number, consistency and movability of the axillary lymph nodes are observed The nodes may be fixed to the underlying axillary structures or to the overlying skin. The transverse diameter of the largest axillary node is estimated in centimeters

Palpation is inaccurate in determining whether or not axillary lymph nodes contain metastatic lesions These nodes may enlarge from causes other than malignant disease

Diagnosis The diagnosis of cancer of the breast is often obvious from the presence of one or more of the foregoing findings If these findings are definite, the carcinoma has reached an advanced stage It is desirable to find a tumor in the breast so small that biopsy is indicated for making a positive diagnosis. Histologic study is the certain way of making a correct diagnosis

Early in the course of cancer of the breast metastasis tends to take place to the cervical and axillary lymph nodes, ribs and spinal column, liver, pelvis and abdominal viscera; and the skin

Bilateral Cancer of the Breasts. Bilateral cancer of the breasts occurs frequently enough so that the presence of a known cancer of one breast requires study of the other breast, particularly if there is a lump in the second breast Bilateral carcinoma occurring simultaneously is rarely found, but it does happen The carcinoma of the remaining or second breast may occur years after the first one has been removed Often it is difficult for the pathologist to be positive whether the malignant lesion in the second breast is primary there or secondary or metastatic from the first breast involved

Inflammatory Carcinoma of the Breast. Inflammatory carcinoma of the breast implies the coexistence of carcinoma and inflammation. The fact is, however, that these breasts usually do not contain evidence of inflammation on histologic study. The condition often occurs in lactating breasts, but this incidence is by no means constant.

Pain is a commoner first symptom in the so-called inflammatory carcinoma of the breast than in the usual instance of carcinoma

Physical examination reveals diffuse induration extending through much or all of the breast. So dense is the inflammation that often a definite tumor cannot be palpated.

Inflammatory carcinoma frequently enlarges the breast Enlargement of one breast may be the first intimation of trouble. The skin of the breasts is red and often edematous Axillary lymph nodes are always palpable. Despite extensive involvement of the breasts, ulceration of the skin is rare. When present, it occurs very late in the course of the disease. All studies on inflammatory carcinoma of the breast indicate a poor prognosis.

Part Two

The Systemic Diseases

In medicine, the term system has one of three meanings (1) a set or series of parts or organs which unite in a common function; (2) a whole bodily organism which unites in a common function and (3) a school or method of practice.

In this part of this book the first meaning is applied. Hence, the term systemic disease refers to disease affecting one or all parts which are related to perform a certain function; for instance, disease of the lungs, trachea, bronchi, and pleura, one or all of them, is disease of the respiratory system

9

DISEASES OF THE THORACIC WALL, PLEURAE, MEDIASTINUM, BRONCHI AND LUNGS

THE THORACIC WALL

The lungs and heart may be hampered in the performance of their functions by diseases of their own as well as by being influenced by diseases of the body as a whole. Hence the condition of these organs often serves as a guide to the general bodily functioning, and therefore the state of the respiration and circulation is continually being examined for purposes of diagnosis, prognosis and treatment It is for these reasons that the physical examination of the thoracic organs occupies a prominent place in diagnosis by physical means. Once a physician has gained even moderate skill in examination of the thorax he has gone a long way on the road of rendering good service to patients These statements do not imply that an examination by physical means is all that is necessary in diagnosing diseases of the thorax They simply mean that examination of the thorax by physical means is always necessary. At times the circumstances may be such that examinations by any other means are not feasible and then examinations by physical means may have to suffice for the basis of treatment.

Shape of the Thorax. The bony chest is subject to defects in development as well as to disease and injury and to deformities due to these causes.

The thorax is conical in shape, being small above and large below. In infancy the anteroposterior and the transverse diameters are nearly equal. At the age of 2 years the chest has become oval, and in adults the transverse diameter is one fourth greater than the anteroposterior

Variations in the shape of the thorax are mainly the result of disease. In childhood, rachitic disease (rickets) produces a lateral flattening and a projection of the sternum If the sternum projects markedly, it constitutes what is known as pigeon breast, the thorax in such a condition being longer from front to back than from side to side In this disease also there may be a depression on each side of the sternum, the back is rounded

ints of junction of the ribs and

Chapter 6

Directional Terms and Topography of the Thorax and the Respir Organs. For the sake of convenience in description and record, the t arbitrarily is divided into various regions and marked by longitudinal lines.

The Longitudinal Lines. Seven longitudinal lines are used. They run paralle the long axis of the body Three are situated anteriorly (Fig. 9-1) and two poster

1. The *median line* is the midline of the body. This runs down the middle sternum anteriorly and the middle of the back posteriorly
2. The *parasternal line* runs parallel to the edge of the sternum and midwa tween it and the midclavicular line
3. The *midclavicular line,* also called the *mammary line,* is a longitudinal line ing through the middle of the clavicle This usually passes ⅗ to ⅘ inch (about 2 cm.) medial to the nipple.
4. The *anterior axillary line* passes through the anterior fold of the axilla
5. The *midaxillary line* passes through the middle of the axilla
6. The *posterior axillary line* passes through the posterior fold of the axilla
7. The *scapular line* passes longitudinally through the lower angle of the sca

The Regions of the Thorax. In the middle of the surface of the thorax ante there are three regions.

1. The *suprasternal region* is the part above the sternum between the sternocl mastoid muscles. It is the suprasternal notch.
2. The *upper sternal region* extends from the suprasternal notch to a line d opposite the third costal cartilages.
3. The *lower sternal region* is behind the second piece of the sternum from third costal cartilages down

Anteriorly but *laterally* to the middle regions of the thorax there are four regions:

1. The *supraclavicular region*, above the clavicle. This includes the supraclavicular fossa.

2. The *infraclavicular region*, below the clavicle down to the upper edge of the third rib.

3. The *mammary region*, from the upper edge of the third to the upper margin of the sixth rib. This extends laterally from the edge of the sternum to the anterior axillary fold and has the nipple nearly in its center.

4. The *inframammary region* extends from the upper margin of the sixth rib to the lower margin of the thorax.

Laterally on the thorax between the folds of the axilla there are two regions:

1. The *upper axillary region* extends down to the upper border of the sixth rib

2 The *lower axillary region* extends from the upper border of the sixth rib to the lower edge of the thorax

Posteriorly there are four scapular regions.

1. The *suprascapular region* is above the spine of the scapula

2. The *scapular region* is the part covered by the body of the scapula below its spine.

3 The *infrascapular region* is the part of the thorax below the scapula between its angle and the lower edge of the chest.

4. The *interscapular region* is the part between the posterior edge of the scapula and the median line.

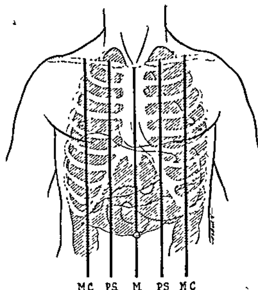

Fig 9-1 Topographic areas of the anterior thorax M C, midclavicular, P S, parasternal, M, median or midsternal When used, designate right or left side of patient

The Pleurae. These form closed spaces which line the thorax (parietal pleura) and cover the surface of the lungs (visceral pleura) The pleurae are completely in contact with the lungs only when the lungs are fully expanded In ordinary breathing the lungs are not completely expanded, hence the edges of the pleurae fall together and so prevent the formation of a cavity This collapsing of the pleurae takes place mainly along the anterior and lower borders of the lungs

The apex of each pleura is attached to the tip of the cervical fascia There is an attachment to the first rib and to the scalenus anticus muscle which prevents collapse (Fig 9-2)

The upward extension of the pleura is about on a plane with the superior surface of the first rib The posterior portion of the pleura is higher than its anterior portion at the anterior end of the first rib The pleura extends 1 inch (about 2 5 cm) above the level of the superior surface of the clavicle.

The top surface of the pleura is stretched in the form of a plane which is almost on a level with the superior surface of the first rib From the top the pleura slopes forward behind the sternoclavicular joint to meet the pleura of the opposite side at the level of the second costal cartilage The pleura covering each lung then descends to opposite or a little below the fourth costal cartilage, where it diverges toward the side, thence to the upper border of the seventh costal cartilage near its sternal junction, thence downward and outward to the lower border of the seventh rib in the mammary line, the ninth rib in the axillary line, and the twelfth rib posteriorly. The scapular line intersects the lower edge of the pleura at the eleventh rib.

The Lungs. When the lungs distend, they expand mostly downward but also, to a lesser extent, laterally and anteroposteriorly, owing to the elevation of the ribs which is due to the traction of the muscles upon them Breathing is performed mainly by the intercostal muscles and diaphragm As the diaphragm descends, the air is drawn into the

turbinate bones, all of which obstructions interfere particularly with nasal respiration

Diseases of the lungs and pleurae alter the shape of the thorax. These common alterations are considered in the section on examination of the lungs and pleurae.

Topographic Examination of the Thorax. On inspection of the chest it may appear normal, rounded or flat. One side may be larger than the other, and the intercostal spaces may be obliterated or retracted. The gross abnormalities are observed and recorded.

The clavicles and the sternum are subcutaneous and can readily be felt beneath the skin. The point of junction of the first and second pieces of the sternum is opposite the second costal cartilage. It forms a distinct prominence, the angulus sterni or angle of Louis

The tip of the xiphoid or ensiform cartilage can be felt even in the obese patient The top of the sternum is opposite the lower edge of the second thoracic vertebra. The angulus sterni is opposite the fifth thoracic vertebra The tip of the ensiform cartilage is opposite the eleventh thoracic vertebra. Above the upper end of the sternum is the suprasternal notch or depression, below its lower end is the infrasternal depression or epigastric fossa.

The sternoclavicular joint possesses an interarticular cartilage between the clavicle and the sternum which separates them sufficiently to allow the formation of a distinct depression, which can be felt. Below the inner end of the clavicle the first rib can often be seen and felt.

The cartilage of the seventh rib is the last to articulate with the sternum The tenth rib is the lowest which is attached anteriorly, the eleventh and twelfth being shorter and floating ribs. The intercostal spaces are wider anteriorly than posteriorly and the third is the widest

In men the nipple is usually in the fourth interspace or on the lower border of the fourth rib and on a line a little to the outer side of the middle of the clavicle. In women the mammary gland reaches from the third to the seventh rib

The operation of paracentesis, or tapping for pleural effusion, is often done in the sixth interspace in the midaxillary line or posteriorly (see Back in Locomotion, Chapter 6)

Directional Terms and Topography of the Thorax and the Respiratory Organs. For the sake of convenience in description and record, the thorax arbitrarily is divided into various regions and marked by longitudinal lines.

The Longitudinal Lines. *Seven longitudinal lines are used. They run* parallel with the long axis of the body. Three are situated anteriorly (Fig. 9-1) and two posteriorly:

1. The *median line* is the midline of the body This runs down the middle of the sternum anteriorly and the middle of the back posteriorly.
2. The *parasternal line* runs parallel to the edge of the sternum and midway between it and the midclavicular line.
3. The *midclavicular line,* also called the *mammary line,* is a longitudinal line passing through the middle of the clavicle This usually passes ⅗ to ⅘ inch (about 1 to 2 cm) medial to the nipple.
4. The *anterior axillary line* passes through the anterior fold of the axilla
5. The *midaxillary line* passes through the middle of the axilla.
6. The *posterior axillary line* passes through the posterior fold of the axilla.
7. The *scapular line* passes longitudinally through the lower angle of the scapula

The Regions of the Thorax. In the middle of the surface of the thorax anteriorly there are three regions:

1. The *suprasternal region* is the part above the sternum between the sternocleidomastoid muscles. It is the suprasternal notch.
2. The *upper sternal region* extends from the suprasternal notch to a line drawn opposite the third costal cartilages.
3. The *lower sternal region* is behind the second piece of the sternum from the third costal cartilages down

are not due so much to a bulging or to a retraction of the lungs as to the atrophy of the fatty and muscular tissue in tuberculosis and to the muscular tension in emphysema.

In coughing, the apex of the lung does not bulge into the neck above the clavicle, as it appears to do, but remains below the plane of the top of the first rib. The appearance of bulging is caused by the movements of the trachea in the median line and of the muscles laterally This is noticeable particularly in the platysma and omohyoid muscles In quiet breathing the posterior belly of the omohyoid lies about level with the clavicle, but in coughing it rises 1 or 2 cm. above it The intercostal membranes and muscles are kept tense by the constant elevation of the ribs due to the muscular tension.

OUTLINE OF THE LUNGS. *Apex.* The apex of each lung has its highest point opposite the posterior extremity of the first rib (Fig 9-2). It then follows the plane of the top of the first rib down to the sternoclavicular joint immediately above the junction of the cartilage of the first rib with the sternum The anterior end of the first rib is about 2 inches (5 cm.) lower than the posterior The upper edge of the clavicle is 1 inch (about 2.5 cm) above the anterior end of the first rib and 2 5 cm below the head of the first rib, hence the apex of the lung rises 1 inch (about 2 5 cm.) above the clavicle, and it lies behind its inner fourth This distance will vary in different individuals with the obliquity of the ribs The more oblique the ribs, the greater will be the distance between the level of the top of the clavicle and that of the neck of the first rib The top of the lung, however, never is above the level of the neck of the first rib There is no appreciable difference in the height of the right lung and the left lung (Fig. 9-3).

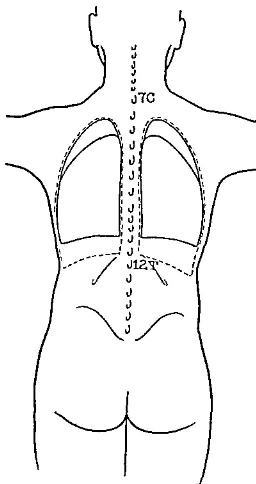

Fig 9-3 Outlines of the lungs—posterior view

Anterior Border. From the sternoclavicular joint the borders of the lungs pass downward and inward until they touch or almost touch in the median line at the angle of Ludwig opposite the second costal cartilage Below this the right lung extends a little across the median line and the left recedes slightly away from it. The right lung leaves the sternum opposite the sixth costal cartilage to which it has gradually descended

The left lung on reaching the level of the fourth costal cartilage curves outward and downward across the fourth interspace to a point about 1 inch (2.5 cm.) to the inner side of the nipple in the fourth interspace. From this point it goes downward and inward across the fifth rib and interspace to the top of the sixth rib about 1⅕ inches (3 cm) to the inner side of the nipple line This isolated tip of lung just above the sixth rib over the apex beat of the heart is called the lingula

Lower Border. The lower edge of the lung varies in different individuals, and in the same individual according to the amount of inflation In quiet respiration it

trachea and lungs, and the pressure within the thorax is lowered to zero or to a m[illegible] quantity, so that if it were not for its bony framework the chest would collapse. [illegible] framework is sufficiently strong to retain its shape despite this pressure if the breathin[illegible] normal and the thoracic walls are healthy. When, however, obstruction of the air passa[illegible] is present in young patients, the deformities funnel breast, pigeon breast or variations

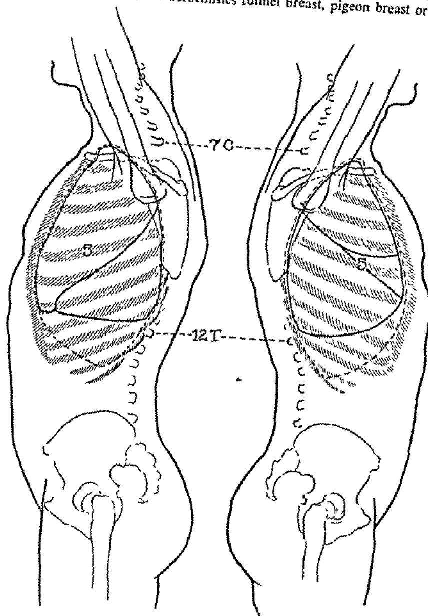

Fig 9-2. Lateral views of the extent of the pleura and outline of the lobes of the lungs

these are produced. These deformities are also produced by weaknesses in the bony thorax, such as occur in rickets

Enlargement of the chest posteriorly is impossible because of the support of the ribs, vertebrae, and strong back muscles. Enlargement downward is allowed by a descent of the diaphragm, hence the fullness of the abdomen in those affected with emphysema and, conversely, the flatness of the abdomen in those whose lungs are contracted In the region of the apices the thorax is closed by the deep fascia, which spreads from the trachea, esophagus, muscles and great vessels and blends with the pleura to be attached to the first rib. In disease this level with the plane of the first rib is not materially altered. The apparent fullness of the supraclavicular fossae and intercostal spaces in emphysema and the increased depth of these hollows in pulmonary tube ulosis

tumor, a single myeloma and giant cell tumor must be considered, and when multiple regions are seen, metastatic malignant disease or multiple myelomas are possible.

Malignant tumors of the sternum may arise in the sternum and its neighboring cartilage. They grow posteriorly, encroaching on the anterior mediastinum. Likewise tumors may arise from the spinal column and its surrounding structures and extend anteriorly and encroach on the posterior mediastinum They may extend laterally, displacing the lung and pleura and occupying the apical or other thoracic regions. At first, from either point of origin, these tumors remain circumscribed. Later they extend through their own capsule and invade or surround the mediastinal structures. These tumors may extend to the pleura and lungs, and may metastasize to the lungs, liver, spleen, kidneys and other organs.

The symptoms of malignant tumors of the sternum are pain, cough, dyspnea, tumefaction and mediastinal pressure These symptoms develop and progress more slowly than when lymphosarcomas are present in the mediastinum and producing similar symptoms.

Physical examination may reveal a mass near the site of origin, especially if the tumor arises from the sternum or its cartilaginous attachments. Any or all of the physical signs of mediastinal tumors with compression phenomena may be elicited.

Both anteroposterior and lateral roentgenograms are useful in demonstrating the size and situation of the tumor At times the roentgenographic study may be helpful in establishing the nature and origin of the growth The presence of hemorrhagic pleural fluid may indicate the presence of malignancy in the thoracic cavity.

Surgical removal, in the early stages, is the preferred treatment.

SYMPTOMS OF RESPIRATORY DISEASE

The symptoms often significant of pulmonary disease are pain in the chest, cough, expectoration, hemoptysis, cyanosis, dyspnea, stridor and hoarseness.

Pain in the Chest Pulmonary tissue and the visceral pleura are devoid of the sense of pain The parietal pleura is richly supplied with sensory nerves from the intercostals Stimulation or irritation of the parietal pleura produces a sharp pain which can be located with fair accuracy over or near the point of stimulation. The diaphragmatic pleura is also sensitive, but stimulation of it never produces local pain, the pain is always referred The central part of the diaphragm is innervated by the phrenic nerve, and the afferents from here enter mainly the third and fourth cervical posterior nerve roots; the peripheral part of the diaphragm is innervated by the lower intercostals, and the afferents enter the seventh to twelfth posterior nerve roots Pain, therefore, from the central portion of the diaphragm is referred to the neck and the upper part of the shoulder, from the outer parts of the diaphragm it is referred to the lower part of the thorax, lumbar region and abdomen The stronger the pleural stimulation the wider is the area of the referred pain, and it may even extend to the other side of the body.

There are many types of pain which may be felt in or about the thorax, all of which are commoner than those arising in the pleurae and lungs For instance, there are muscular pains due to strain or even tearing of muscle fibers; the boring pain of an eroding aneurysm; root pains attending tabes dorsalis, syphilitic meningitis, tumors of the cord, herpes zoster, spondylitis and other lesions which involve the posterior nerve roots, the substernal pain on swallowing which may be associated with esophageal obstruction. There are the pains of angina pectoris and aortitis Pains in the breast may be considered to be pains in the chest. Referred pains from perforating peptic ulcers are by no means uncommon. The pains of true intercostal neuritis are common, but difficult to diagnose.

is about opposite the sixth cartilage and rib from the sternum to the mammary line, opposite the eighth in the midaxillary line, the tenth in the scapular line, and the eleventh near the vertebrae. The lowest part of the lung is on the side at the midaxillary line or a little posterior to this, but the line from here posteriorly, although rising slightly, is nearly horizontal

THE FISSURES AND LOBES OF THE LUNGS The left lung has one fissure and two lobes, an upper and a lower The right lung has two fissures and three lobes, an upper, a middle and a lower (Fig. 9-2).

The relations of the fissures to the surface are variable. They generally appear posteriorly at different levels, the right main fissure being lower than the left. The fissure of the left lung appears at the side of the vertebral column at a variable point extending from the third rib to the upper border of the fifth rib. In the axillary line it is at the fifth rib, although it may be slightly higher or lower, and it ends beneath the sixth rib or the interspace above or below, anywhere from 2⅖ to 4⅓ inches (about 6 to 11 cm) from the midline

The main fissure of the right lung leaves the vertebral column opposite the fifth rib or at the root of the spine of the scapula. The fissure tends to follow the fifth rib, being beneath the rib or beneath its interspace in the midaxillary line and ending at the sixth rib in the mammary line

The subsidiary fissure of the right lung leaves the main fissure in the posterior axillary line opposite the fifth rib and running horizontally forward ends near the sternum at any point between the third and fourth interspaces.

Diseases of the Thoracic Wall. The diseases of the thoracic wall are usually secondary to those primarily affecting the skin and subcutaneous tissues, muscles, bones and nerves, or to diseases originating from the structures within the thoracic cage

Tumors of the Thoracic Wall. Both benign and malignant tumors occur in the thoracic wall. Lipomas are of common occurrence over the shoulders and back and in the axilla. Likewise fibromas occur in the same situations. Cysts may arise from the cutaneous glands over the back. Pigmented nevi in aging persons are of common occurrence over the back

The primary malignant tumors of the thoracic wall arise in the skin, subcutaneous tissues, the breast and the bony framework. The malignant tumors of the *skin* are those common to glabrous skin. They are carcinomas and melanoepitheliomas Carcinomas when present are often situated over the shoulders and scapular regions, originating in sebaceous glands which abound here The tumors of the soft tissues which undergo malignant change are fibromas and hemangiomas These tumors are described in the section on diseases of the skin. A common malignant tumor of the thoracic wall is carcinoma of the breast The tumors which originate in the *bony framework* are multiple myelomas, Ewing's tumors of the ribs, osteogenic growths and chondrosarcomas, all of which are rare and are considered in this text with tumors of the bones

Metastatic tumors of the ribs are frequent. They may be clinically silent, causing no symptoms, or at times they may be the first manifestation of malignant disease when a pathologic fracture occurs. Malignant tumors of the breast, prostate gland and thyroid gland, and hypernephromas are especially likely to cause metastasis to the ribs and spinal column. Cancer of the breast in women and cancer of the prostate in men are most likely to cause pathologic fracture of the ribs

The symptoms of metastatic tumors of the ribs are dull aching pain and, most frequently, intercostal neuralgia. When the lesion is in the upper ribs, the pain often has a brachial plexus distribution. The patient may discover a swollen or tender region which persists.

Often the results of examination are negative if there are no fractures present. Examination by physical means *is never diagnostic of rib tumors.* Diagnosis *is* established by roentgenographic examination. When the tumor is su[illegible]'s

blood from the stomach, *hematemesis*. The bloody sputum of hemoptysis is bright red, contains froth and does not contain food. When in doubt about whether there has been hemoptysis or hematemesis, ask the patient whether the blood came from the lungs or the stomach The patient can often answer this question correctly and may even state correctly the side of the chest from which the hemoptysis came

When blood is intimately mixed with mucus in the sputum, the color varies according to the relative quantities of these two constituents and the length of time after they have been mixed. Thus, in pneumonia, the sputum may have a brick-dust tint (rusty sputum), or it may be outspokenly hemorrhagic Mucohemorrhagic sputum is also met with in hemorrhagic infarction of the lung and in neoplasm.

The so-called prune juice sputum (an unnecessary term) is a serohemorrhagic sputum. It is met with when a croupous pneumonia is complicated by edema of the lung A peculiar mucohemorrhagic sputum of sticky consistency, said to resemble currant jelly (another unnecessary connotation) has been described in those who have neoplasm and sometimes in pulmonary syphilis

Small streaks of bright blood in sputum otherwise of mucous character usually originate in the upper air passages or in the mouth

Blood-stained saliva is often brought to the physician by the hysterical and by simpletons It is usually a thin fluid, of stale odor and of brownish red color.

Color of the Sputum Sputum may be of different colors, owing to the admixture of various coloring matters *Black sputum* is seen in coal-miners and iron-workers; *blue sputum* is occasionally seen in workers in dye works, *green sputum* is met with in pneumonia with jaundice, sometimes in caseous pneumonia, and occasionally in pyocyaneus infections, *yellow sputum* may be due to hematoidin in pulmonary abscesses, or to bile when hepatic abscesses break into the lung In chronic passive congestion of the lung in cardiac disease, a *yellowish red* tint may appear, owing to the large number of pigment-containing cells—heart-failure cells—in the sputum.

Odor of the Sputum Usually stale, the odor of sputum may become putrid from decomposition in the mouth or in the air passages (fetid bronchitis, bronchiectasis, pulmonary gangrene) There is no odor more sickening than that of fetid sputum

Consistency of the Sputum The consistency of sputum depends on the relative amount of mucus it contains, in asthma, and sometimes in pneumonia, the sputum is so tenacious that it must be wiped from the mouth.

Protein Content of the Sputum. Sputum arising chiefly from increased secretion of the bronchial mucous membrane, as in asthma and in bronchitis, is poor in protein, whereas sputum arising in inflammations of the lung substance itself, for instance, or in transudations, such as pulmonary edema and chronic passive congestion, is rich in protein. The protein loss in the sputum, except in hemoptysis, is not of sufficient quantity to be of practical importance The urea content of the sputum closely parallels the concentration of urea in the blood

Particulate Matter in the Sputum Fragments, occasionally pieces of pulmonary tissue, may be coughed up in gangrene or in pulmonary abscess Pieces of *tumor* and *tumor cells* often appear in the sputum The finding and identification of tumor cells in the sputum are valuable diagnostically and these are searched for in all instances of suspected malignant disease of the lungs or bronchi

Sometimes branched fibrinous casts of the bronchi are coughed up in fibrinous bronchitis, in croupous pneumonia or in diphtheria. These are recognizable with the unaided eye They are of no particular diagnostic significance. When they are small, if desired these casts may be isolated by shaking the sputum with water.

Curschmann's spirals, Charcot-Leyden crystals, tuberculous lenses, and Dittrich's plugs are terms which are the remnants of former days and convey no implications of definite pathologic significance In the decomposing sputum of putrid bronchitis, of bronchiectasis, and of pulmonary gangrene, small yellowish white masses may be present

COUGH A cough consists of a forcible, explosive expiration during which the glottis is first closed and then quickly opened. The current of air passing between the vocal cords gives rise to a noise that is at first of high pitch, becoming lower as the glottis opens.

A cough is a defensive mechanism which, when properly used, helps to cleanse the larynx, the trachea and the larger bronchi. The sensory stimulus passes up the vagus to the cough "center" in the medulla oblongata which lies close to the respiratory center.

Unnecessary coughing injures the mucous membranes of the air passages. Violent coughing can injure the elasticity of the lung, especially in its upper parts Coughing exerts an important influence on the circulation. As results of coughing, the intrathoracic pressure is increased, the inflow of venous blood is hindered, and the outflow of arterial blood is favored, so that the arterial pressure may momentarily be increased. This sudden heightening of the blood presure may lead to arterial rupture in atherosclerosis or in aortic aneurysm, it accounts for the conjunctival hemorrhages in any patient who has a violent cough. Prolonged violent coughing may cause extreme soreness and tenderness in the epigastric muscles.

When nothing is expectorated, the cough is dry or empty, as in cutaneous or in pleural irritation.

A hacking or frequently recurring feeble cough indicates continuous slight irritation, it is met with in acute and chronic catarrh of the upper air passages. Violent paroxysms of coughing, difficult to allay, are common in convalescence from influenza. The so-called goose cough or brassy cough of aortic aneurysm is characteristic only of a mediastinal tumor with pressure on the recurrent laryngeal nerve. The whoop of whooping cough has only to be heard once to be afterward easily recognizable However, the whoop is not limited to whooping cough It occurs in any severe irritating cough in either children or adults There is a laryngitis caused by Pfeiffer's organism occurring in adults which often is accompanied by the whoop. These affections are often termed second attacks of whooping cough

In summary it is well to repeat Pottenger's definition of the mechanisms of cough, which consist of (1) a sensory disturbance in the larynx through the superior laryngeal nerves, (2) a closure of the glottis through the superior and inferior laryngeal nerves, (3) a contraction of the expiratory muscles (internal intercostals and abdominal) through the thoracic spinal nerves, and (4) relaxation of the inspiratory muscles (diaphragm, external intercostals, intercartilaginous muscles of the shoulder girdle) through the cervical and thoracic spinal nerves

THE SPUTUM. The sputum expectorated on hawking or coughing consists of a mixture of secretions from the mucous membranes with pus, blood or other materials given off from the respiratory apparatus The secretions come from the mucous membranes of the larynx, trachea and bronchi, pharynx and back of the nose. In addition to these secretions, the sputum contains saliva, secretions from the mucous membranes of the mouth, and food particles

The amount of sputum is extremely variable and depends on the disease process present The largest amounts are met with in certain bronchial affections; in large bronchiectatic or phthisical cavities, in pulmonary edema; or when abscesses or empyemas break into the bronchi. In such cases the sputum may be brought up in mouthfuls (as much as 1 to 2 liters daily).

Varieties of sputum are designated according to the predominating constituent present. Four main varieties of sputum are described: mucous, purulent, serous and bloody. Other forms of sputum are admixtures of these, for example, mucopurulent, and mucohemorrhagic.

Sometimes there is expectoration of pure blood, which is termed *hemoptysis*. In hemoptysis, the blood is coughed up; it is distinguished from the vomiting of

whether from primary heart failure or from heart failure secondary to fibrosis of the lungs and the pneumoconioses, emphysema, or arteriosclerosis

Deficient aeration of the blood such as occurs in tracheal obstruction, bronchial asthma, uncomplicated emphysema and in the acidosis of uremia or diabetes is an important cause of dyspnea. The dyspnea thus produced is enhanced by myocardial insufficiency with an ensuing degree of pulmonary congestion. In pulmonary congestion the lungs become stiffened and less distensible, and therefore a reflex, mechanical factor of dyspnea is added

Dyspnea may also occur as a hysterical manifestation, either in the form of attacks of deep sighing respirations, usually following some emotional disturbance, or occasionally even as paroxysms of hyperpnea, with deep and labored breathing. If the resulting hyperventilation persists long enough, alkalosis with tetany ensues

Certain clinical varieties of dyspnea associated with certain phases of respiration are commonly recognized Inspiratory dyspnea is due to obstruction of the larynx or trachea which slows the respiratory rhythm by prolonging and deepening inspiration; it causes apprehension and often anguish to the sufferer, and is accompanied by a collapse, during inspiration, of the soft parts above the sternum and below and between the ribs

Expiratory dyspnea is due either to an advanced loss of pulmonary elasticity, as in emphysema, or to generalized bronchial spasm, as in asthma. Dyspnea of effort is a symptom of many types of respiratory disease. It is a principal sign of the disturbances of pulmonary circulation caused by cardiovascular diseases.

Orthopnea in Pulmonary Disease. Orthopnea is dyspnea present even when the patient sits up It represents a serious exhaustion of the respiratory reserve which consists of an urgent need for oxygen and an accumulation of carbon dioxide in the blood Compensation is striven for by an increased depth of respiration; this is obtained by prolonging and deepening respiration, with little or no increase in rate Orthopnea attends laryngeal and tracheal obstruction, the diffuse bronchial spasm of asthma, and the diffuse spasmodic obstruction of the earliest stage of bronchiolitis. In all conditions attended by an increased rigidity of the lungs, for instance, in the pneumonias, in massive collapse of the lung, in all forms of pulmonary congestion or edema, and in diffuse miliary tuberculosis breathing is shallow and rapid

STRIDOR. Air passing in and out of a partially obstructed larynx or trachea may produce a harsh, vibrating noise This vibrating noise is termed stridor. It is a noise produced in the larger air passages in the same way that rhonchi are produced in the smaller ones Stridor may occur during any part of the respiratory cycle It is ordinarily most obvious in inspiration and during coughing, imparting a harsh, high-pitched quality to the cough The obstruction of the larynx and trachea may be intrinsic, as, for example, by a diphtheritic membrane, or it may be extrinsic, as, for example, a mediastinal tumor, or from kinking of a bronchus such as may be produced by localized fibrosis of the lung. The obstruction of a main bronchus is attended by a wheeze, not stridor

HOARSENESS In disease inside the thorax the larynx is often secondarily affected, either by local inflammation or by paralysis due to pressure on the recurrent laryngeal nerve The dysphonia which ensues may vary from a mild huskiness to aphonia. The extent of the loss of voice is not a measure of the seriousness of the lesion.

Acute laryngitis causes a dysphonia which passes off as the inflammation resolves The voice may be altered by extrinsic factors also—nasal obstruction, tracheal obstruction, pharyngitis, and chronic disease of the lungs Aphonia or soft whisper may occur in neurotic patients.

Hoarseness which persists in persons more than 40 years old may be due to a tumor of the larynx, either benign or malignant

They consist of particles of tissue or of small masses of pus which have undergone decomposition in the lungs or in the bronchi Sputa containing these materials have a foul, fetid odor.

Small, soft, yellowish white particles consisting of fungi are common in pulmonary tuberculosis and in chronic bronchitis. In actinomycosis of the lungs these particles are termed sulfur bodies. Pulmonary stones may be present in sputum, and when the patient inquires about them a correct answer should be given These stones are portions of calcified lymph nodes.

CYANOSIS IN PULMONARY DISEASE. The blue color of the skin and mucous membranes in cyanosis is due to the presence of sufficient reduced hemoglobin in the capillaries to give the color which shows through the skin A minimal content of 5 gm of reduced hemoglobin per 100 ml. of blood is necessary before the blue color is apparent In profound anemia, however, with a hemoglobin content of less than 5 gm., the amount of reduced hemoglobin cannot reach this minimal content, even in the presence of marked anoxia, and thus the profoundly anemic patient will not be cyanosed. The greater the amount of reduced hemoglobin, the deeper the cyanosis. It is best seen in the lips, nose, cheeks, ears, fingers and toes It can be temporarily abolished by pressing out the blood from the part. The intensity of the color depends also on whether the small peripheral vessels are dilated or contracted.

The blood in the capillary vessels may contain an excess of reduced hemoglobin either because it left the heart in this condition, or because there is an abnormal, excessive change of oxyhemoglobin to reduced hemoglobin while the blood is passing through the peripheral capillary system

Abnormally slow passage of the blood through the peripheral capillaries allows the tissues to take more oxygen from it than usual, and so to produce more reduced hemoglobin Slowing of the peripheral circulation is a normal response to cold, and mild degrees of local blueness are compatible with good health. When capillary stasis or poor blood flow is associated either with general circulatory failure or with some form of local vascular paralysis it is indicative of serious disease.

It is not always easy to determine the cause of cyanosis in a particular patient, whether it is respiratory or circulatory or a combination of both. When the capillaries are engorged, the pulse full, the flow rapid, there is in addition to the deficient oxygenation in the lungs an associated carbon dioxide retention, with peripheral *vasodilatation and an inadequate circulation In some instances* of inadequate circulation the cyanosis is deep and florid, and the patient breathes heavily, while in others the skin may be pale, cold and wet, with leaden livid cyanosis, indicating poorly filled capillaries in a patient who has respiratory and circulatory failure, a rapid feeble pulse and quick, shallow breathing

Cyanosis may also result from the formation in the blood of certain derivatives of hemoglobin Methemoglobin is produced by large doses of drugs such as chlorates, coal-tar derivatives and sulfonamides These drugs may also determine the formation of sulfmethemoglobin, which gives rise to a leaden type of cyanosis.

DYSPNEA IN PULMONARY DISEASE. Dyspnea is characterized by difficult, painful or disordered breathing. Hyperpnea is increased breathing. A healthy person *is not conscious of any increase in respiration until the normal rate is doubled.*

The obvious causes of dyspnea are many, for instance the various diseases of the lungs and pleura, cardiac failure, anemia, the acidosis of uremia or diabetes, increased intracranial pressure and hysteria. The important causes are: chemical alterations in the blood flowing through the respiratory center, and local conditions in the lungs which make them more rigid and less easily distensible and cause rapid and shallow breathing. Rigidity or decreased distensibility of the lungs is by far the more usual factor in the dyspnea. It determines the dyspnea of pneumonia, of pulmonary edema and of massive collapse of the lungs. Pulmonary congestion, with consequent rigidity of the pulmonary tissue, is the cause of cardiac dyspnea,

whether from primary heart failure or from heart failure secondary to fibrosis of the lungs and the pneumoconioses, emphysema, or arteriosclerosis.

Deficient aeration of the blood such as occurs in tracheal obstruction, bronchial asthma, uncomplicated emphysema and in the acidosis of uremia or diabetes is an important cause of dyspnea. The dyspnea thus produced is enhanced by myocardial insufficiency with an ensuing degree of pulmonary congestion. In pulmonary congestion the lungs become stiffened and less distensible, and therefore a reflex, mechanical factor of dyspnea is added.

Dyspnea may also occur as a hysterical manifestation, either in the form of attacks of deep sighing respirations, usually following some emotional disturbance, or occasionally even as paroxysms of hyperpnea, with deep and labored breathing. If the resulting hyperventilation persists long enough, alkalosis with tetany ensues.

Certain clinical varieties of dyspnea associated with certain phases of respiration are commonly recognized Inspiratory dyspnea is due to obstruction of the larynx or trachea which slows the respiratory rhythm by prolonging and deepening inspiration; it causes apprehension and often anguish to the sufferer, and is accompanied by a collapse, during inspiration, of the soft parts above the sternum and below and between the ribs.

Expiratory dyspnea is due either to an advanced loss of pulmonary elasticity, as in emphysema, or to generalized bronchial spasm, as in asthma. Dyspnea of effort is a symptom of many types of respiratory disease. It is a principal sign of the disturbances of pulmonary circulation caused by cardiovascular diseases

Orthopnea in Pulmonary Disease Orthopnea is dyspnea present even when the patient sits up It represents a serious exhaustión of the respiratory reserve which consists of an urgent need for oxygen and an accumulation of carbon dioxide in the blood. Compensation is striven for by an increased depth of respiration; this is obtained by prolonging and deepening respiration, with little or no increase in rate. Orthopnea attends laryngeal and tracheal obstruction, the diffuse bronchial spasm of asthma, and the diffuse spasmodic obstruction of the earliest stage of bronchiolitis In all conditions attended by an increased rigidity of the lungs, for instance, in the pneumonias, in massive collapse of the lung, in all forms of pulmonary congestion or edema, and in diffuse miliary tuberculosis breathing is shallow and rapid

STRIDOR. Air passing in and out of a partially obstructed larynx or trachea may produce a *harsh, vibrating noise* This vibrating noise is termed *stridor*. It is a noise produced in the larger air passages in the same way that rhonchi are produced in the smaller ones Stridor may occur during any part of the respiratory cycle. It is ordinarily most obvious in inspiration and during coughing, imparting a harsh, high-pitched quality to the cough The obstruction of the larynx and trachea may be intrinsic, as, for example, by a diphtheritic membrane; or it may be extrinsic, as, for example, a mediastinal tumor, or from kinking of a bronchus such as may be produced by localized fibrosis of the lung The obstruction of a main bronchus is attended by a wheeze, not stridor.

HOARSENESS In disease inside the thorax the larynx is often secondarily affected, either by local inflammation or by paralysis due to pressure on the recurrent laryngeal nerve The dysphonia which ensues may vary from a mild huskiness to aphonia. The extent of the loss of voice is not a measure of the seriousness of the lesion.

Acute laryngitis causes a dysphonia which passes off as the inflammation resolves. The voice may be altered by extrinsic factors also—nasal obstruction, tracheal obstruction, pharyngitis, and chronic disease of the lungs. Aphonia or sóft whisper ma[illegible] otic patients

[illegible] ich persists in persons more than 40 years old may be due to a tun[illegible] r, either benign or malignant

EXAMINATION OF THE LUNGS AND PLEURAE

In studying clinically the condition of the lungs and pleurae, the physician employs the aids of inspection, palpation, mensuration, percussion, auscultation and exploratory puncture The roentgenologic examination of the lungs and pleurae, often aided by the intrabronchial use of radiopaque substances, is more precise and reliable than any other examination by physical means. The bronchoscopic examination is more precise for the purposes of diagnosis in certain instances than any other examination

The Respiratory Movements. The lungs make no active movements of their own during respiration, but simply follow passively the movements of the wall of the thorax and of the diaphragm Two main types of inspiratory expansion of the thorax are seen In the *costo-abdominal* type the expansion is due chiefly to the descent of the diaphragm, and less to the elevation of the ribs In the *costal* type the opposite is the case, the expansion being due chiefly to elevation of the ribs

The diminution in size of the thorax during expiration depends normally on the elasticity of the lungs and ribs, *not on muscular contraction.*

The times occupied by inspiration and expiration, respectively, are approximately equal, and there is no pause between the two.

FREQUENCY AND RHYTHM OF THE RESPIRATIONS. The number of breaths taken by healthy adults varies between 16 and 20 per minute. The rate in disease may be increased or decreased.

Increase of the frequency of respiration (dyspnea or tachypnea) is met with in most diseases of the respiratory system, in many diseases of the heart, and in those diseases of the abdomen that hinder the movements of the diaphragm In dyspnea the number of respirations may reach 40, 60, or more per minute In certain diseases of the nervous system excessive tachypnea may occur in paroxysms

Mechanisms of the production of tachypnea are discussed under Heart Disease (Chapter 10)

Slowing of the respiration (bradypnea) may be met with in affections of the brain or of its membranes, in irritations of the respiratory center in the medulla; in severe infections and in uremia.

Cheyne-Stokes Breathing. In this form of respiration, periods of complete cessation of the respiratory movements alternate with periods in which the respirations slowly increase in frequency and volume to a maximum, and then again decrease until they cease

The phenomenon is met with in many normal persons while asleep and therefore is inconsequential in illness despite the fact that it is observed in an *exaggerated* form in many patients who are seriously or critically ill During the apneic phase these very ill patients are sleepy, and the pupils are contracted and nonreactive; as the respiratory movements return, the psyche awakens, and the pupils dilate and again become responsive

In *Biot's breathing* the respiratory pauses are long (from 5 to 30 seconds or more), in periods which may recur more or less regularly or wholly irregularly

Dyspnea is observed normally on exercise and in disease either of the lungs or of the circulatory apparatus As dyspnea increases, the patient sits up in bed, with his head, arms and thorax held rigid, panting for breath; and the *condition is* then termed orthopnea.

DETERMINATION OF THE VOLUME OF THE INSPIRED AIR AND OF THE EXPIRED AIR (SPIROMETRY). The measurement of the air entering and leaving the lungs in each phase of respiration can be made by means of a spirometer.

Certain terms which have been established in spirometry should be understood, since these terms may be employed in description of minute output of the heart determined by gasometric methods (carbon monoxide), and occasionally on patients

who have heart disease. By *vital capacity* is meant the amount of air that, after the deepest possible inspiration, can be expelled on full expiration; in healthy men it varies from 3,000 to 4,000 ml ; in women it varies between 2,000 and 3,000 ml The vital capacity is smaller in old age, as well as in all diseases of the respiratory system

Tests of pulmonary function offer a method of appraising pulmonary disabilities objectively. They are of value in determining the absence of pathologic alterations in some of the nonpulmonary types of dyspnea, as seen in neurocirculatory asthenia and hysteria; the course of various pulmonary diseases can be followed objectively; and the preoperative use of the tests will indicate fairly accurately the results of such surgical procedures as collapse therapy, lobectomy, and pneumonectomy

The increased interest in pulmonary physiology since surgical operations on the lungs and the heart have become commoner has brought about a revision of the terminology used to describe the various components of respiration.

Inspiratory Reserve (Complemental Air). This measures the maximal amount of air which can be drawn into the lungs, using the resting expiratory level as the starting point. Normally this amounts to 3,000 ml.

Expiratory Reserve (Supplemental Air) This measures the maximal amount of air which can be expired, using the resting expiratory level as the starting point Normally this amounts to 1,000 ml

Residual Air (Residual Capacity) This represents the air remaining in the lungs following a maximal expiratory effort This quantity cannot be measured spirographically and its determination depends on measuring the amount of nitrogen displaced by breathing 100 per cent oxygen

Functional Residual Capacity This represents the quantity of air remaining in the lungs after the completion of a quiet respiration It is the sum of the residual air and the expiratory reserve

Maximal Breathing Capacity This is a measure of the maximal volume of air that can be breathed in a unit of time The maximal breathing capacity differs from the vital capacity in that it expresses a time relationship The same information can be obtained by measuring the vital capacity and relating it to the time required for expiration.

The amount of air taken in during a minute of quiet respiration varies from 5 to 7 liters

The vital capacity of the lungs enlarges on bodily exercise and in pathologic states accompanied by dyspnea.

INTERCOSTAL RETRACTION AND EXPANSION On inspection of the thorax it is well to observe the rate of the respirations and record it. The progression of expansion of the lungs is followed during inspiration with particular reference to the lack of filling and consequent expansion in any part of the lung and especially at the apices In the adult in a normal state of nutrition there is no noticeable expansion or retraction in the intercostal spaces.

The Diaphragmatic Phenomenon (Litten's Sign). In emaciated adults the respiratory movements of the lower margin of the lungs can sometimes be observed as a furrow, descending during inspiration over the intercostal spaces, especially in the lower part of the right side of the thorax (Litten's sign) This is due to the separation of the diaphragm from the thoracic wall when it contracts; before the lungs can follc [illegible]

adh[illegible]
formation

Mensuration of the Thorax. By passing a tape around the thorax, just above the nipples, the patient's arms being held out from the sides, the circumference of the thorax is measured On physical examinations for entrance to the army or navy, and for life insurance, this value is used as a measure of the development of

the thorax, and serves as a clue to the general constitution of the person. In healthy young men the circumference should exceed 32 inches (about 81 cm).

More important as regards the state of the lungs themselves is *the difference in circumference on deep inspiration and on deep expiration.* Normally this difference amounts to about 2⅘ inches (7 cm.) or more

The comparison of the *circumference of each of the two halves* of the thorax shows normally a difference of from 0 5 cm. to 2 5 cm. in favor of the right side In an asymmetric thorax, owing to unilateral expansion or retraction slight differences in circumference of the two halves of the chest can be easily recognized

Exact records of the form of the thorax are made with a *cyrtometer.*

Palpation of the Thorax Over the Lungs and Pleurae. A part of the palpation of the thorax is the testing of the vocal fremitus, the vibration of the voice propagated to the thoracic wall through the bronchi and pulmonary tissue. The test is made by placing the two hands on symmetric portions of the thoracic wall and asking the patient to repeat in a deep voice "1, 2, 3," or "99." In health the vocal fremitus perhaps is more marked on the right than on the left side In women the vocal fremitus is weaker than in men. Vocal fremitus sometimes is helpful in deciding whether dullness over the lower part of the thorax is due to infiltration of the lung or to pleural effusion; increased vocal fremitus indicates better conduction from the larynx to the lung surface (infiltration), while enfeeblement or abolition of the fremitus suggests pleural effusion or pneumothorax. However, in massive pneumonia, with plugging of the bronchus, the propagation of the voice may be temporarily interfered with, again, in pleural effusion, there may be less diminution of the vocal fremitus than might be expected because pleural adhesions, uniting the lung to the wall of the thorax, may favor the conduction of the voice tremor, or an atelectasis, due to the pressure of the exudate, may increase the vocal fremitus more than the effusion weakens it

Percussion Over the Lungs and Pleurae. In percussion a shock is given by the percussion stroke which gives rise to sounds that vary with the elasticity (capacity for vibration) of the parts struck; the greater the elasticity, the more marked is the production of sound

PRINCIPLES OF PERCUSSION. Airless bodies enter into sound-producing vibration only when they are rigid or in a certain state of tension. In the human body, bones alone correspond to such a state

The sounds yielded by soft parts when percussed depend on the air or gas content If the air or gas is contained in large cavities, it is set into vibration, and along with it the wall of the cavity is started vibrating; if the air is distributed and confined throughout the whole tissue, as in the lungs, the air and the tissue vibrate together on percussion. Percussion then permits of an approximate delineation of the limits of juxtaposed airless and air-containing structures.

DIRECT PERCUSSION. The fingers are arranged in a plane with the middle finger stiffened and slightly flexed toward the palm and, to produce the sounds, deliver the

Fig 9-4 Direct percussion employing the stiffened *middle finger*

Fig 9-5 Direct percussion with the end of the middle *finger.*

stroke directly on the surface of the thorax, with the middle finger, without any intermediary plessimeter (Fig. 9-4). A better method is to use the end of the finger as in Figure 9-5.

INDIRECT PERCUSSION. In this method, the blow, instead of being struck directly on the body surface, is delivered on some intermediate body placed upon the part under study. This intermediate body is called a plessimeter or pleximeter. As a *plessimeter* the middle finger, called a plessimeter finger, is used (Fig. 9-6) To ascertain the condition of the structures behind the clavicle, the clavicle itself often is used as a plessimeter.

Fig 9-6. Indirect percussion employing the middle finger as a plessimeter

The plessimeter finger is most often used because it permits judgment of the feeling of resistance, thus yielding some information accessory to the percussion sounds. It is easy to approximate the finger to the surface such as the intercostal spaces and supraclavicular fossae.

As a *percussor*, or *plessor*, it is customary to use the middle finger of the right hand, flexed to an obtuse angle at the two distal terminal joints, and slightly flexed at the proximal joint of the finger (Fig 9-6). The stroke is delivered entirely from the wrist, the forearm remaining in position. With practice one soon learns how best to deliver the stroke. As a rule, the percussing finger should be allowed to rebound immediately from the plessimeter after it has struck, in order that the plessimeter may freely vibrate with the part beneath. In gentle percussion the plessimeter finger should lie in smooth contact with the part under study; for deep percussion it may be firmly pressed against this part.

In *orthopercussion* the force of the blow is directed exactly perpendicular to the surface

The *strength of the percussion stroke* should vary greatly according to the conditions of the examination. When the soft parts over the organ under examination are thick, the stroke must, of course, be harder to set that organ in vibration

In the determination of so-called *deep or relative dullness* of the heart, however, it is necessary to use a somewhat stronger stroke, though even here ones does best to use percussion of medium force rather than the very strong percussion so often employed

THE INTENSITY AND QUALITY OF THE SOUNDS PRODUCED ON PERCUSSION. In percussion of the thorax, as elsewhere, attention is directed, regarding the sounds produced, to their *loudness*, their *pitch*, and their *clang* or *timbre*.

Comparative Percussion of the Lungs. In health the pulmonary resonance on percussion varies somewhat over different regions of the thorax, corresponding to the variable thickness of the soft parts and to the variable volume of lung beneath. In some places the sound is louder and fuller than in others. By repeated percussion of the healthy chests of different persons there gradually become fixed in mind memories of the normal sounds heard, and of the normal resistance felt, on percussion over the lungs It is learned how much muffling, or dulling, of the sound may be due to varying degrees of obesity and to different degrees of muscular development The percussion sound is always clearer in front and at the sides than behind. In fat persons the resonance on percussion over the back may be impossible to evaluate.

It is always well to compare the percussion sounds yielded by symmetric parts

on the two sides of the chest, beginning with percussion of the supraclavicular fossae above and passing downward on the two sides over the several intercostal spaces, making sure to percuss always with the same force and to direct the stroke in the same way.

The breathing should be quiet and normal during percussion. The loudest sounds are normally met with between the third and the fifth ribs in front.

It is wasted time to percuss over the tympanitic space of Traube (fourth to sixth rib on), owing to the presence of the stomach under the left side and front of the lower part of the thorax In comparative percussion of the two sides of the chest, asymmetries of the two sides of the thoracic wall are important. A slight grade of scoliosis may affect the sounds.

The loudness of the percussion sounds depends, essentially, on the amount of air or gas in the organ examined.

The terms clear and dull refer to the *intensity* of the sound Clear and dull are used, clinically, *in a different sense from that of ordinary speech. Clinically, reference to the* loudness of sound is to the amplitude of the sound waves that strike the ear drum. This intensity depends on the capacity for vibration and the strength of the percussion blow. In comparative percussion, therefore, use exactly the same force, and avoid confirming a preconceived opinion by unequal force of the percussion blows, for unequal force will produce unequal sounds and dullness may thus be simulated

The *pitch* of a tone depends on the number of vibrations per second The greater the number of vibrations, the higher the tone Percussion sounds are always *noises,* composed of a large number of individual *tones.* The lowest tones are met with over the distended lungs in pulmonary emphysema A percussion sound, therefore, that contains very low tones is usually loud, clear and full.

The ear should be carefully exercised in the appreciation of the lower tones on percussion When one tone is dominant, as in tympanitic sounds, the height of its pitch is easily recognizable to one who has a good tone-pitch sense. The recognition of differences in the pitch of the dominant tone in tympanitic sounds lies at the basis of the recognition of alterations in pitch.

In general it may be said that a *tympanitic sound* over a lung, except in Traube's space, which is situated in the lower part of the left lung, indicates an abnormal condition within the thorax such as pulmonary cavities, bronchiectatic cavities, abdominal viscera dislocated into the thorax, or a change in the structure of the lung that leads to loss of the tension of the alveolar walls, for example, atelectasis of the lung, from bronchial occlusion, or from compression due to high position of the diaphragm, large pericardial effusions, or pleural effusions, or in edema of the lung, in certain stages of pneumonia when the alveolar septa have changed in texture from the inflammation, though the air content is not yet essentially diminished, or in bronchial pneumonia, in which the bronchi in airless tissue may give rise to a tympanitic note

A *metallic* or *amphoric sound* on percussion depends on the presence of high overtones accompanying and obscuring a low fundamental tone It arises in large gas-containing cavities with tense walls. It will appear in the blown-up stomach if the distention is sufficiently increased. To grow familiar with this sound, it may be elicited by thumping over the cheek after the mouth has been so strongly distended by air that the tympanitic sound, present on less distention, disappears

A *cracked-pot sound* (or metallic clink) arises, on strong percussion, if air or gas is thereby driven out of a cavity through a narrow opening

THE FEELING OF RESISTANCE ON PERCUSSION It may be possible to draw more precise conclusions from percussion if the examiner not only listens, but feels with the finger which is being percussed The sense of resistance *felt by the fingers* on percussion varies with the compressibility of the part percussed. It is readily admitted that percussion areas do not correspond to anatomic projections, but by practice of finding these areas in the normal thorax, pathologic changes can often be recognized and the clinician is better for having this experience.

The Upper Limits of the Pulmonary Resonance on Percussion. Normally the upper limits are in the same position on the two sides. On each side the limit extends for a distance of from 1⅕ to 1⅗ inches (about 3 to 4 cm) above the clavicle at the level of the spine of the sixth or seventh cervical vertebra, and, behind, goes over the edge of the trapezius muscle obliquely downward and mediad into the posterior medial pulmonary limit at the level of the spine of the second thoracic vertebra (Krönig's fields of pulmonary resonance at the apices).

Normally the upper margin of the lung reaches a point, above the clavicle, corresponding to the position of the tubercle on the first rib, which can be felt on palpation between the heads of the sternocleidomastoid muscle

The Lower Limits of the Pulmonary Resonance on Percussion. These can be approximately determined by percussion

The lower limit of the pulmonary resonance varies with the phases of respiration and with the position of the patient On forced inspiration the boundaries may descend ⅘ to 1⅕ inches (about 2 to 3 cm) below the level found in quiet breathing In the dorsal decubitus the lower margin is ⅖ to ⅘ inch (about 1 to 2 cm.) below its position in the sitting posture, in the lateral decubitus, that of the upper lung may descend 1⅕ to 1⅗ inches (about 3 to 4 cm) lower

Abnormal Position of the Boundaries of the Lungs The determination of the pulmonary limits may, in pathologic states, show a general expansion, a displacement only of the lower boundaries, a general contraction, or a displacement of either the lower or the upper limit

General expansion of the pulmonary limits is met with in chronic emphysema and in the temporary inflation of the lungs due to tracheal or laryngeal stenosis, diffuse bronchitis and bronchiolitis, or asthma The lower limit may be lower than normal from compensatory emphysema of the lower part of the lung when the upper part is diseased, for example in apical tuberculosis, or when the opposite lung is diseased

General contraction of the pulmonary limits is met with when the total amount of air-containing tissue in the lungs is diminished from any cause, that is, prevention of entrance of air into the lung or compression of the lung from thoracic tumors or abdominal distention

The *lower limit of a lung may be higher* than normal when the diaphragm is high, as in abdominal distention or in retraction of a lung, or when parts of the lung are deprived of air, as in bronchostenosis A very common cause for displacement of the lower limit of pulmonary resonance upward is the accumulation of fluid in the pleural cavities When the pleura is nonadherent, the fluid tends to accumulate chiefly in the lateral parts, the line of the dullness does not, as a rule, run horizontally, but in a curve, the highest point of which lies approximately in the posterior axillary line, descending rather abruptly in front, and more gradually behind (S-shaped line of Gardner)

Retraction of the upper limit is most often due to pulmonary tuberculosis The retraction of the apex is usually first demonstrable at the upper medial margin in front

DULLNESS AND FLATNESS ON PERCUSSION. The percussion sound is dull in all conditions in which the air content of the lung percussed is less than normal

When the lung is separated from the thoracic wall by fluid, there must be at least 500 ml to yield dullness on percussion An immediate change of the dullness with change of position indicates the simultaneous presence of air and fluid

Auscultation of the Lungs. On auscultation of the lungs the examiner listens (with the aid of a stethoscope) to the sounds that accompany inspiration and expiration and the voice sounds that are audible over the thorax. Application of the ear to the thoracic wall is no longer employed unless the stethoscope has been left at home Under these circumstances a great deal of information may be gained.

The voice sounds are better heard with the naked ear than with the aid of a stethoscope, but the breath sounds and, especially, some of the modifications that these undergo in disease, as well as some of the sounds that accompany them, are better recognized and localized by the use of the stethoscope.

From "Current Comment" in the *Journal of the American Medical Association* (Dec 24, 1949), on the auscultatory respiratory murmur the following comment is quoted:

A new appraisal of auscultation, which is based on clinical experience and facts in physics and physiology discovered since Laennec's time, is claimed to show that the respiratory murmur is composed of sound vibrations originating in all component parts of the respiratory mechanism. It is now maintained that the respiratory murmur cannot be caused by air rushing through the larynx and impinging on the bronchial walls and dilating the air cells because the lungs always contain residual air which stops the force of the incoming current and causes the air to enter the finer bronchi and air cells by diffusion The sound vibrations causing the vesicular murmur are said to originate in the respiratory mechanism in the anterior, lateral and lower portions of the thorax, where the air cells predominate, the musculature is light and the bony cage is elastic. That part of the respiratory mechanism which normally causes the bronchial murmur is found in the superior portion of the thorax and is most distinct posteriorly. Here the sound vibrations are produced by the air current, the larger bronchi, a comparatively small amount of pulmonary tissue and air cells, a heavy musculature and the least elastic portion of the bony cage

THE BREATH SOUNDS. The breath sounds present over the alveolar masses of the lung are called *vesicular breathing* The breath sounds present over the larger air tubes during respiration are termed *bronchial breathing.*

In disease states, when there is secretion of excessive mucus, swelling of the bronchial mucous membrane, or fibrinous exudation on the surfaces of the pleurae, certain accessory or *adventitious sounds* arise These sounds are termed rales, crepitation, friction sounds.

The breath sounds normally are loudest just beneath the clavicles. The sounds are feebler over the apices

MODIFICATIONS OF VESICULAR BREATHING. Accentuated vesicular breathing is heard normally in children, and hence is often spoken of as puerile breathing Puerile breathing may be audible until puberty, more often in girls than in boys

Accentuated breathing is heard in the neighborhood of infiltrated regions, especially at the apex, in incipient pulmonary tuberculosis, and in a healthy lung close to a consolidating region, at the beginning of pneumonia.

Sometimes there is *prolongation of the expiratory sound* of vesicular breathing so that this becomes as long as, or even longer than, the inspiratory sound A prolongation of the expiratory part of the vesicular breath sounds often indicates an expiratory dyspnea, such as emphysema, asthma or bronchitis. If the distribution is limited to the base of the right lung, it may indicate the beginning of congestive heart failure

If the inspiratory sound, instead of being continuous, is interrupted so as to consist of two or more parts, the inspiration assumes a jerking or saccadic character; it is *cog-wheel breathing.* Cog-wheel breathing is often met with in persons of feeble musculature, in nervous people, and in children after crying

BRONCHIAL BREATHING. Bronchial breathing is audible in healthy persons over the spinous process of the seventh cervical vertebra, corresponding to the position of the bifurcation of the trachea, and thence downward to the spine of the fifth thoracic vertebra.

The loudness of bronchial breathing is not important. It is the aspirating, hollow or reverberating character of the sound that is peculiar, and it is often well marked when the sounds are weak. The expiratory portion of the sound in tubular breathing

may, and usually does, approach the inspiratory sound in intensity; its duration is great. In some instances, however, expiration is inaudible in tubular breathing.

Pathologic Bronchial Breathing. The solidifications of the lung over which pathologic bronchial breathing becomes audible include (1) infiltrations due to pneumonia, tuberculosis, or hemorrhagic infarction; (2) compression behind pleural exudates and tumors, and (3) atelectasis The solid regions, under ideal conditions, which are seldom present, must be either near the surface or be connected with it by means of a good sound-conducting medium, moreover, the communicating bronchi must be open Cavitation resulting from the destruction of air sacs, over which pathologic bronchial breathing may become audible, includes bronchiectatic cavities, tuberculous cavities, and larger emphysematous cavities. The communicating bronchi must be open, and the cavities must be near the surface, or must communicate with it by sound-conducting media.

MIXED BREATHING OR BRONCHOVESICULAR BREATHING The term mixed breathing or bronchovesicular breathing is used too frequently and perhaps, in some instances, for the purpose of mental hedging.

Over normal lungs or pleuritic exudates, or when loud rales are present, the respiratory murmur may be so feeble that the character of the breath sounds cannot be recognized "Bronchovesicular breathing" simply means the presence of both bronchial and vesicular elements in the breath sounds

ORIGIN OF THE VOICE SOUNDS. In auscultation of the voice sounds two processes are important (1) the production of fundamental tones in the larynx, where the vocal cords of the glottis act like a reed instrument, and (2) the process of articulation, in which the different tones produced in the larynx are modified by changes in shape of the oral cavity, and adjacent cavities, the larynx itself being unable to articulate The oral cavity, in association with the laryngeal and nasal cavities, constitutes a resonating chamber As such, it intensifies that particular tone or overtone of the sound produced in the larynx the wavelength of which corresponds in resonance to the dimensions of the cavity Variations in the shape of the cavity will modify its function as a resonating chamber in that it will vibrate in unison with notes of different wavelengths or pitch Thus, through changes in the resonating chamber, different overtones may be intensified or weakened and corresponding changes in the voice sounds produced In whispering there is articulation of the breath sounds only, the glottis being passive and giving rise to no loud tones

When auscultation is made over the healthy lungs of a person pronouncing the number "99" in a voice of low pitch, the audible voice sounds are nearly everywhere weak and muffled instead of being loud and clear like those audible over the larynx. When loud, clear voice sounds are audible directly over the bronchi of the healthy thorax, the condition is known as bronchophony The term bronchophony includes all such sounds audible in health and all degrees of clearness greater than this in disease

If it is observed that the sounds have become less clear than formerly, especially if they suddenly disappear over an area, occlusion of the bronchi is often the cause of the disappearance of the sounds

Increased clearness or distinctness of the voice sounds is termed pathologic bronchophony. This term is applied when sounds as clear as, or clearer than, those heard over the upper thoracic part of the spinal column in health are met with in any other part of the thorax. The phenomenon is due either to increased conducting power or to increased reflecting power of the lung tissue The conducting power of the spongy structure of the lung is increased by any change that makes the pulmonary structure more homogeneous

Whispered bronchophony is sometimes clearer than that of the spoken voice. The terms pectoriloquy and whispered pectoriloquy are sometimes applied when the sounds are very clear, apparently close to the ear, and exactly circumscribed.

A special kind of definite bronchophony known as egophony is sometimes heard above the level of the fluid in large pleural effusions that cause partial compression

and narrowing of the bronchi. The voice sounds have a definite nasal quality which is rhythmically intensified and interrupted.

Over large cavities containing air, and especially over a pneumothorax, the voice sounds may have an amphoric, metallic, ringing quality.

Auscultation of the voice sounds yields information comparable in large part to that afforded by palpation of the vocal fremitus; when the voice is not strong enough or deep enough to yield a palpable fremitus, auscultation of the sounds may give information not otherwise obtainable. It is well to learn how to correlate and do these two examinations synchronously.

ACCESSORY OR ADVENTITIOUS RESPIRATORY SOUNDS In addition to the natural breath and voice sounds and the changes these undergo in disease, certain sounds occur, inside and outside the lung, wholly additional to these. Of such adventitious respiratory sounds, two great groups are distinguished: (1) rales or crackles and rhonchi, and (2) friction sounds All rales are caused by moisture in the lungs but they are classified as (1) rhonchi and (2) rales.

Rhonchi and Rales. These sounds arise during respiration from interference with movements through the air passages of the air breathed. These interferences with the movements of the breathed air result from the presence of fluid, mucus, serum, blood, or water in bronchi and in cavities, leading often to the formation of air bubbles which may interfere with the movement of different masses of mucus or secretion and thus add noise The sudden separation of sticky mucous membranes or the passage of air through abnormal local narrowings produces sounds.

These sounds may be loud or feeble, numerous or few, they are often inspiratory in time, though they may be audible during expiration On testing for the presence of rales, the patient is asked to take a deep breath and end it with a short cough. It is important to notice whether the rales disappear or are modified on coughing.

Rhonchi are long, whistling or snoring sounds that die away slowly They are due to the vibrations of tough mucus attached to the walls of the bronchi, or to the passage of the air through lumina narrowed by spasm of the bronchioles or by swelling of their mucous membrane. They are often accompanied by palpable vibration of the thoracic wall The sounds, when low pitched, have a snoring character and are termed sonorous rhonchi If these sounds are high pitched, they are more whistling or piping in character and are termed sibilant rhonchi

Rales arise when fluid is present in the air passages They are crackling or bubbling sounds. In contrast with the more continuous, chiefly expiratory, sibilant and sonorous rhonchi, rales are interrupted, bubbling or crackling sounds, heard during inspiration.

The *moist rales* are sometimes classified according to the apparent size of the ... those next in ... ound of the ... of the hair between the fingers close to the ear.

The *crepitant rale,* no matter in which condition it is met with, is believed to be due to the opening up of collapsed air sacs or minute bronchioles. It is distinguishable from other moist rales chiefly by the short duration, or small size, of each of the successive crepitations, and by the large number of crepitations attending each inspiration.

Ringing or consonating rales are bubbling sounds arising in a cavity or in a larger bronchus and well propagated to the surface through infiltrated pulmonary tissue; the higher tones are strengthened through resonance in the bronchi. This ringing character of a rale is therefore of diagnostic importance in infiltrations of the lung Consonating rales occur under the same conditions in general as does bronchial breathing.

Metallic ringing rales occur under conditions similar to those in which a metallic clang on percussion and metallic bronchial breathing occur The so-called *metallic tinkling* is a single sound heard intermittently by the physician or the patient. It occurs most often in pyopneumothorax or in large tuberculous cavities.

PLEURAL FRICTION SOUNDS. Pleural friction sounds arise during respiration from the rubbing together of the pleural surfaces, roughened by some pathologic process such as fibrinous or inflammatory exudates.

These sounds are heard most frequently when the pathologic process is situated between the costal pleura and the pulmonary pleura; between the pulmonary pleura and the mediastinal pleura; or between the pulmonary and the diaphragmatic pleura The sounds may be fine, coarse or scratching or creaking They may be intense or feeble.

The softer, gentler friction sounds may sound like vesicular breathing; the coarser, crackling friction sounds may sound like rales. The pleural friction sounds, however, are usually accompanied by pain, they sound as if they were close to the ear, and they are intensified by pressure of the stethoscope They are often accompanied by a palpable friction fremitus. They do not disappear, nor are they modified on coughing Pleural friction sounds indicate the presence of a dry pleurisy in the region in which they are audible Friction sounds sometimes become audible in tumors of the pleura, or when the pleura is abnormally dry, as in severe dehydration.

Near the heart pleural friction may be heard which is synchronous with the heart's action, owing to the rubbing of the pericardial pleura against the adjacent pulmonary pleura. This is termed pleuropericardial friction

SUCCUSSION SPLASH COIN SOUND When the pleural cavity contains both liquid and air, and the patient is given a vigorous shaking while the physician listens to the thorax, a splashing sound is heard. This is termed the succussion splash The patient may be able to hear it and to produce it at will and may complain of it Even if this splash has never been heard by the physician, he should know about it in order to interpret it if the patient complains of it This splash is different from the one similarly produced in the stomach

A succussion splash is usually due to pneumothorax, it is occasionally heard in the absence of pneumothorax, when large cavities exist in the lung

The coin sound is hardly a diagnostic test It is elicited by percussing with coins on the back of the thorax at the level of a cavity and by listening with a stethoscope in the front of the thorax at the same level

Roentgenographic Examination of the Thorax. The *efficiency and limitations* of roentgenographic examination of the chest in the diagnosis of thoracic diseases by this means have been summarized by Rigler essentially as follows.

1 Pulmonary edema can be detected before the onset of appreciable symptoms or within a few hours thereafter It is detectable in the roentgenogram from 6 to 12 hours before the appearance of physical signs

2 Pleural effusion in amounts of 100 ml or more can be detected if proper technic is used This amount is compared with 500 ml of fluid necessary for demonstration by physical examination

3 Bacterial pneumonias give roentgenographic evidences of their presence in as short a time as 2 hours, most frequently within 6 hours, and almost invariably within 12 hours of the onset of definite symptoms.

4. Atypical or virus pneumonias may give no distinctive roentgenographic findings for 24 to 48 hours after the onset of symptoms.

5 Pulmonary tuberculosis of the ordinary chronic type is not demonstrable until 8 to 20 weeks after the exposure

6 Acute miliary tuberculosis invariably produces symptoms before the development of roentgenographic signs The latter may not be present for as long as 7 weeks after the onset of symptoms

7. Nodular lesions such as those produced by metastasis or nodular tuberculosis are demonstrable when their diameter is 3 mm or larger Even lesions of this size will

not be seen if multiple films in various positions are not made or if the lesions are unfavorably located

8 Metastatic lesions of miliary size, such as those produced by miliary tuberculosis, may not be visible until numerous or large in size.

9. All metastatic lesions are roentgenographically visible before the onset of symptoms or physical signs

10. Bronchogenic carcinoma almost invariably gives positive roentgenographic signs when symptoms are present, if thorough examination is done. There are a few exceptions to this rule In most instances roentgenographic evidences of abnormality will be present before the onset of any respiratory symptoms due to bronchogenic carcinoma Complete examination is necessary, however, to establish these evidences.

Reliability of interpretation of roentgenographic evidence of diseases of the lungs and pleurae requires training, skill and experience. The clinical management and even the details of treatment in thoracic disease often are based on the interpretation of shadows observed in roentgenograms. Physicians may hesitate to question the reliability of this method of examination, although they realize well the fallibility of other diagnostic procedures that appear less mysterious to them. Shadows that appear on films must be interpreted in pathologic terms.

An editorial in the *Journal of the American Medical Association* of December 29, 1951, discussed a project designed to record different opinions in regard to interpretation of roentgenograms of the chest. The project involved the recording of opinions by six experienced observers, three of whom were radiologists and three of whom were internists, regarding the stability of lesions of pulmonary tuberculosis as recorded on single roentgenograms (postero-anterior projections) taken at intervals of three months Each observer independently reported his opinion of each pair of films and subsequently re-examined the same series of films without reference to his original interpretation. The data thus recorded were analyzed by competent biostatisticians who were able to measure the inconsistencies of interpretation and relate the scores of each reader with the others and with his own previous opinions It was revealed that a second observer will disagree with the first observer in about one third of all instances and, what is more surprising, when the same observer reviews the same film a second time after an appropriately long interval, he will find disagreement between his two opinions in about one fifth of cases studied

These results in no way decrease the recognized necessity and value of roentgenographic examination of the chest, but they do emphasize the fact, long known to many physicians experienced in thoracic disease, that clinical management of thoracic disease must be based on many types of clinical and laboratory data and not on roentgenography alone Furthermore, the single postero-anterior chest film frequently does not constitute complete roentgenologic examination, for fluoroscopy, stereoscopy, tomography, and specially projected views may add materially to the accuracy of the examination in special circumstances However, with all of this information available, it must be realized that there is no substitute for the clinician, whose difficult task involves synthesis of different types of evidence in formulating a program of management for the patient In dealing with thoracic disease, the physician relies heavily on roentgenography, but realizes that the opinion of the dynamic status of pulmonary disease would in some instances be reversed if a second expert viewed the films or even if the same observer should submit a second opinion after he has forgotten the first report.

COMMENT

On examining the thorax by the physical methods heretofore described, it is appropriate to try to draw inferences regarding the air content of the underlying lungs and the physical state of the pleural cavities. Subsequently it is wise to seek the pathogenetic explanation of these physical conditions of the lungs and pleurae The methods of physical examination by employment of the special senses of the

physician are now known to be only approximately accurate but physicians, when trained, are grateful for the information they may give.

DISEASES OF THE PLEURA

Pleural Pain. The *parietal pleura* is innervated by sensory nerve fibers from the intercostal nerves. The ability to locate sensory impressions by the pleura is acute everywhere but seems more highly developed in the anterior and lateral aspects

The *peripheral regions of the diaphragmatic pleura* derive their sensory nerves from the phrenic nerve and the last six intercostals. The intercostals supply a peripheral rim of the diaphragmatic pleura, which is 1 to 3 inches (2.5 to 7.6 cm.) wide anteriorly, and a segment corresponding to the posterior third of the membrane. Irritation of the areas gives rise to pain in the lower part of the thorax on the same side and in the lumbar region or in the abdomen. The *central portion* is innervated by the phrenic nerve. Irritation of this portion sets up pain in the neck

The afferent impulses reach the cervical cord through the phrenic nerve trunk, and pass thence to the brain where the sensorium registers pain in the somatic segment corresponding to the entrance of the phrenic nerve; thus the pain is a referred pain

Disease or stimulation of the *peripheral or posterior portion of the diaphragm* produces pain which spreads over the lower part of the thorax and epigastrium, at times extending down over all of the abdomen on the same side

Capps has observed that the distribution of the pain depends on the degree of irritation and its prolongation. The more intense the irritation, the greater is the tendency of the pain to spread down over the lower portion of the abdomen, and in an occasional instance it may extend over both sides of the abdomen or to the lumbar region The pain may be associated with detectable hyperalgesia of the skin and superficial tissues on pressure

In some individuals who have diaphragmatic pleurisy the pain is referred to the neck along the area of the trapezius ridge The neck pain is spontaneous or produced by deep breathing or cough and is well localized by the patient with the tip of the finger Pressure over this point is painful

PARIETAL PLEURISY. The pain in pleurisy confined to the *upper lobes of the lungs* is always situated in the upper scapular and shoulder region In *pleurisy over the lower lobes* the pain is commonly restricted to the lateral and anterior aspect of the lower part of the thorax.

Localized pleurisy usually produces a sharp, stitch-like pain on cough or deep inspiration, directly over the region of the pleura involved, provided there is mobility between the parietal and visceral pleurae. Pleurisy without pain, even though a friction rub is present, may occur.

VISCERAL PLEURA The visceral pleura is insensitive

Pleurisy, for the sake of description, has often been referred to as dry pleurisy and wet pleurisy or pleurisy with effusion The nature of the effusion is designated by appropriate combinations of word roots For instance, the term serofibrinous pleurisy implies that the effusion is serous, empyema implies the presence of pus in the pleural cavity; pneumothorax, the presence of air, and hemothorax, the presence of blood

The wet and the dry types of pleurisy do not have etiologic implications, for in reality they may be but phases of the same disease These terms wet and dry are employed to designate the condition of the pleura at a particular time. As pleurisy runs its course, at one time or another it may pass through both the wet and the dry phases Fibrinous or dry pleurisy is the beginning phase of most pleurisies. It is the phase before an effusion into the pleural cavity takes place. After effusion dry pleurisy ceases to exist and there is present pleurisy with effusion If the effusion contains bacteria and is thus infected, the condition is empyema.

Dry Pleurisy. During the course of many diseases, pleurisy without a significant amount of fluid (less than 500 ml.) in the pleural cavity may occur. This is the so-called dry pleurisy. Dry pleurisy often is associated with the beginnings of pneumonia, less frequently with pulmonary abscess, gangrene, carcinoma, or infarctions, or with septicopyemia, rheumatic fever, or chronic nephritis, or it originates by extension from pericarditis, peritonitis, or hepatitis. It has some relation to tuberculosis, occurring sometimes as a primary infection, more commonly as a secondary event to a pulmonary tuberculous focus Carcinomatous metastasis to the pleura is soon followed by pleural effusion.

The first complaint by the patient who has a pleurisy is stitch pains in the side, usually in the neighborhood of the nipple, increased by movement and especially by inspiration, and accompanied by a dry and painful cough. Both cough and respiration are restrained, and the patient bends toward the affected side in order to minimize the pain For the same reason the breathing is hurried, shallow, jerking, and mainly abdominal in type. Fever is usually present, but the temperature seldom exceeds 101 F (38 3 C) and in mild illness may hardly rise above the normal There may be a moderate leukocytosis

On examination of a patient who has pleurisy there may or may not be a palpable friction fremitus. On auscultation a friction rub of variable intensity can be heard. The sound is audible during both expiration and inspiration. The pain and sounds are both increased on pressure over the affected part by the stethoscope or examining hand Hiccough is common Care should be exercised in order to differentiate the sounds of a dry pleurisy from those caused by the skin slipping under the stethoscope, a muscle sound, an atelectatic crackle, and hair on the chest. A dry pleurisy may disappear in a few days or it may last for weeks or even for months

The diagnosis is established from the foregoing findings and from roentgenologic examination.

Wet Pleurisy (Pleurisy With Effusion) Pleurisy with effusion usually follows acute pleurisy There is inflammation of the pleura, associated with a fluid exudate The fluid may be serous, serofibrinous, serohemorrhagic, purulent or putrid

Symptoms. The general symptoms of pleurisy may not be pronounced. The fever is rarely high, it may be continuous or remittent, and the temperature usually falls by lysis In some younger patients, and often in the aged, the onset of pleurisy is insidious There may be no complaint at all, or the patient may complain of nothing more than a little shortness of breath, and on physical examination the true nature of the illness is discovered The most constant general symptom of pleurisy is pain It is sometimes severe at the beginning and is increased by any movement, especially by deep inspiration, coughing or sneezing As soon as enough effusion develops to separate the surfaces of the pleura, the pain ceases. The pain may be referred to the back or the thorax, to the shoulders and arms, and occasionally into the abdomen The pain may erroneously be thought due to intercostal neuralgia, muscular rheumatism, or an acute surgical condition within the abdomen Chills or chilly sensations are common and sweats occur, especially during remissions of the fever and at night Digestive disturbances, including anorexia and nausea and vomit- [illegible] than in those who [illegible] ease in the amount [illegible] rine is the result of [illegible] mouth When the pleural exudate is being absorbed, it rarely can be absorbed fast enough to increase the output of the urine

Examination. When the patient is examined, it is noticed that the posture may be characteristic The patient has less pain, usually, if he lies on the affected side and assumes a diagonal position so as to give more freedom for expansion of the

lung on the healthy side If there is an extensive effusion, there may be orthopnea, and the sitting position is therefore assumed. When the effusion has developed fully, the scapula on the diseased side stands a little high and there is a slight lateral curvature of the spinal column, with concavity toward the healthy side The skin over the affected region may be stretched. On inspiration there is a lagging on the diseased side and the expansion is less The intercostal spaces may be widened, and Litten's phenomenon is absent. The veins of the neck are distended, and the apex beat of the heart is visible and can be seen displaced toward the side opposite the effusion On palpation, there are often changes in vocal fremitus However, an interpretation of vocal fremitus in pleurisy with effusion is difficult. If the effusion reaches any considerable size, on percussion there is dullness or flatness over the effusion. The upper limit of flatness and increased resistance on percussion assumes a typical curve, the upper part of the curve reaching its highest level at the posterior axillary line, whence it curves downward and forward toward the middle line in front. This line sometimes takes the form of a letter S turned on its side The effusion may fill a large part of one pleural cavity, then there is dullness over the whole side of the thorax, from base almost to apex One of the most important signs to be found in examining a patient who has pleurisy with effusion is the increasing intensity of the dullness or flatness or a feeling of resistance on percussing from above downward with the finger tips

On auscultation of the thorax, occasionally there are distant breath sounds or bronchial breathing, bronchophony and often rales may be heard. Accentuation of the breath sounds on the normal side is theoretically present, but practically this distinction usually cannot be made. Egophony is rarely heard

Diagnosis. The diagnosis of pleurisy with effusion is confirmed and often made by a roentgenographic examination Small effusions (less than 500 ml.) which cannot be determined on physical examination always are revealed in roentgenograms of the thorax If roentgen rays are not available, it is advisable to make an exploratory puncture when pleurisy with effusion is suspected to exist. There are several atypical forms of pleurisy with effusion which may exist as circumscribed pockets along the diaphragm or the interlobar portions of the lung, or the disease may be largely confined to the pleura along the mediastinum In any of these atypical forms of pleurisy with effusion, when there are no symptoms of pleurisy, exploratory puncture should always be considered, whether or not the pleurisy is a part of a so-called polyserositis In obscure infections the possibility of a small empyema, which cannot be differentiated from pleurisy with an effusion in any other way except by the exploratory needle, makes this diagnostic procedure imperative.

Bacterial Infections of the Pleura. Empyema. There are many bacteria which are capable of producing empyema Pleural infection is very commonly associated with lobar pneumonia and other pneumococcal infections These organisms gain access to the pleural cavity by extension from the lungs. Likewise tuberculous empyemas occur in pure form or as mixed infections

Empyema may occur during the course of septicemia. The *Escherichia coli* and *Salmonella typhosa* and paratyphi groups of organisms may invade the pleural cavity, particularly if there is peritonitis from these organisms *Pasteurella tularensis* and *Brucella* have been found in empyemic fluid

In still other instances streptococcal, staphylococcal, and pneumococcal empyemas and septicemia may follow a pneumonia or a pulmonary abscess caused by these organisms

The hemolytic streptococcus may reach the pleural space by direct extension from streptococcal pneumonia In some instances, however, the so-called primary empyema is associated with streptococcal bacteremia

Symptoms. Pleurisy is often an early manifestation of pneumonia and is evidenced as a stitch and later a pain in the lower part of the thorax The pain is usually

lost during the course of the pneumonia, not to recur until after the crisis or lysis and then only if there is a pleural infection as a complication of the pneumonia.

Empyema may make its appearance during the course of pneumonia. Often the febrile course of the pneumonia is unduly prolonged. The patient continues to show evidence of toxemia as manifested by weakness and marked leukocytosis, all of which are not evident until the course of the illness is obviously too prolonged for pneumonia.

In the usual instance, however, the empyema occurs after the pneumonia has run its course The patient's temperature and leukocyte count have reached normal limits. After one to two weeks of seemingly satisfactory convalescence, fever again appears, accompanied by profuse sweating. There may or may not be pleural pain The leukocyte count increases and a mild secondary anemia is present.

In those who have both pneumonia and bacteria which precede the pleural infection the diagnosis of *pyemia may have already been made* These patients are critically ill and the mere presence of empyema is of no importance so far as the outcome is concerned.

When a large quantity of foul smelling pus is expectorated there is an extension *of an empyema to form a bronchial fistula* (putrid empyema).

EXAMINATION. On examination of the thorax by physical means there may be a sufficient amount (500 ml.) of pleural effusion present to produce characteristic physical findings More frequently, however, there is too small an amount of pus present to be definitely detected by physical examination.

In other instances the signs of pleural effusion are masked by an underlying pulmonary consolidation

In instances in which surgical treatment is contemplated, the introduction of 10 ml of heavy iodized oil such as Lipiodol is a useful maneuver for determining the size and the most dependent portion of the empyematic cavity The heavy oil sinks to the most dependent portion of the empyema pocket. Postero-anterior and lateral films made with heavy exposure and with the patient in the upright position will indicate the optimal point at which to secure dependent drainage of the cavity

If there have been evidences of rupture of an empyemic cavity into bronchus such as the expectoration of quantities of pus a bronchopleural fistula may be present. The bronchopleural fistula may be demonstrated by the injection of 2 ml of a 1 per cent aqueous solution of gentian violet at the time of the diagnostic thoracentesis. If a fistula exists, the dye will appear in the sputum within 24 to 48 hours after injection

DIAGNOSIS The diagnosis is usually made on the basis of roentgenologic examination. A pleural exudate following pneumonia requires thoracentesis to distinguish between empyema and the sterile effusion which occurs after lobar pneumonias. The aspirated fluid is cultured bacteriologically to demonstrate with certainty the nature of the causative organism The effusion in instances of lobar pneumonia is usually sterile. When the effusion is sterile, no treatment is necessary.

Encapsulated empyema occurs along the pleural surfaces, usually between the lobes of the lungs. The presence of an encapsulated empyema can be established *only by roentgenologic examination and aspiration of the encapsulated pus*

COMPLICATIONS OF EMPYEMA. Infection of the thoracic wall is more likely to develop in those who have large abscess of the lung with profuse external discharge in the putrid type of empyema.

Empyema *necessitatis is the spontaneous rupture of an empyema* through the parietal pleura into the thoracic wall. Eventually the pus breaks through the skin. This condition is rarely encountered except with tuberculous and actinomycotic infections.

A bronchopleural fistula *may make its way to the surface of the thoracic wall,*

or it may drain into the bronchial system. Occasionally an empyema may drain completely by this route and heal spontaneously.

Septicemias and pyemias may either precede or follow empyema.

Tuberculosis of the Pleura. The tuberculous pleurisies occur in (1) those who have recognizable pulmonary tuberculosis and (2) those in whom pulmonary tuberculosis is not recognized There may or may not be a pleural effusion.

Two factors according to Meyers seem to be necessary for the development of a tuberculous pleural effusion: (1) An individual must be sensitive to tuberculin by having or having had tuberculosis. (2) The tuberculin must reach the pleural space. The tuberculin probably reaches the pleural space by the rupture of a small caseous pleural tubercle.

When a subpleural tuberculous focus enlarges and involves the pleural membrane, pleuritis ensues A firm scar binds the visceral and parietal pleurae, forming a pleural adhesion. Occasionally with the onset of pleural inflammation there is a rapid accumulation of serofibrinous exudate in the pleural space, and if the quantity of this exudate is sufficient (500 ml or more), a detectable clinical pleural effusion is present

SYMPTOMS. The general symptoms of pleurisy have been described in discussions of the various forms of pleurisy Dry pleurisy is manifested by pain on respiration The pain is well localized, and is aggravated by deep breathing, coughing, and movements of the thorax The pain from involvement of the diaphragmatic pleural surface is often referred to the posterior midshoulder region of the affected side. The pain often begins abruptly and increases rapidly in intensity.

There may or may not be fever When present, fever is irregular in its appearance and is rarely high. It increases as effusion takes place, and in extremely acute tuberculous pleurisy the temperature may reach 105 F (40.5 C). If a large effusion accumulates, symptoms of increasing intrathoracic pressure appear.

EXAMINATION. Physical examination may reveal reduction of respiratory excursion in the involved half of the thorax. A pleural friction rub or fine dry pleural crackles are frequently heard

On development of pleural effusion the friction rub disappears, to be replaced by the signs of fluid, dullness to flatness on percussion, reduction or absence of breath sounds, voice sounds, and tactile fremitus, and egophony The trachea and other mediastinal structures may be shifted away from the side of the effusion, the degree of displacement depending on the amount of fluid present and the mobility of the mediastinum

In tuberculous pleurisy, except during the very acute manifestations of the disease, the total number of leukocytes is usually within the normal range. During the very acute phase of the disease there is a polymorphonuclear leukocytosis which quickly subsides

A tuberculous effusion when withdrawn is a straw-colored fluid. Leukocytes in the fluid ordinarily number 500 to 3,000 per cubic millimeter, nine tenths of which are lymphocytes The fluid may contain blood.

Guinea pig inoculation or culture on special media for tubercle bacilli should be a routine procedure, but by all methods of examination the results in 30 to 50 per cent of these fluids are negative for tubercle bacilli.

DIAGNOSIS Roentgenologic examination demonstrates evidence of the pleurisy. Tuberculous pleuritis may occur in a patient who has evidence of an active lesion in the lung. In this instance the diagnosis of tuberculous pleurisy is obvious

Dry tuberculous pleurisy, however, may and often does exist in the absence of demonstrable pulmonary tuberculosis and without pleural effusion

A negative tuberculin reaction which remains negative for a few months after the attack is good evidence against a tuberculous etiology.

If a large effusion is present when the patient is first seen, a roentgenologic

lost during the course of the pneumonia, not to recur until after the crisis or lysis and then only if there is a pleural infection as a complication of the pneumonia.

Empyema may make its appearance during the course of pneumonia. Often the febrile course of the pneumonia is unduly prolonged. The patient continues to show evidence of toxemia as manifested by weakness and marked leukocytosis, all of which are not evident until the course of the illness is obviously too prolonged for pneumonia.

In the usual instance, however, the empyema occurs after the pneumonia has run its course The patient's temperature and leukocyte count have reached normal limits After one to two weeks of seemingly satisfactory convalescence, fever again appears, accompanied by profuse sweating. There may or may not be pleural pain. The leukocyte count increases and a mild secondary anemia is present.

In those who have both pneumonia and bacteria which precede the pleural infection the diagnosis of pyemia may have already been made. These patients are critically ill and the mere presence of empyema is of no importance so far as the outcome is concerned.

When a large quantity of foul smelling pus is expectorated there is an extension of an empyema to form a bronchial fistula (putrid empyema)

Examination On examination of the thorax by physical means there may be a sufficient amount (500 ml) of pleural effusion present to produce characteristic physical findings More frequently, however, there is too small an amount of pus present to be definitely detected by physical examination

In other instances the signs of pleural effusion are masked by an underlying pulmonary consolidation.

In instances in which surgical treatment is contemplated, the introduction of 10 ml of heavy iodized oil such as Lipiodol is a useful maneuver for determining the size and the most dependent portion of the empyematic cavity The heavy oil sinks to the most dependent portion of the empyema pocket. Postero-anterior and lateral films made with heavy exposure and with the patient in the upright position will indicate the optimal point at which to secure dependent drainage of the cavity

If there have been evidences of rupture of an empyemic cavity into bronchus, such as the expectoration of quantities of pus a bronchopleural fistula may be present The bronchopleural fistula may be demonstrated by the injection of 2 ml of a 1 per cent aqueous solution of gentian violet at the time of the diagnostic thoracentesis If a fistula exists, the dye will appear in the sputum within 24 to 48 hours after injection

Diagnosis. The diagnosis is usually made on the basis of roentgenologic examination A pleural exudate following pneumonia requires thoracentesis to distinguish between empyema and the sterile effusion which occurs after lobar pneumonias The aspirated fluid is cultured bacteriologically to demonstrate with certainty the nature of the causative organism The effusion in instances of lobar pneumonia is usually sterile. When the effusion is sterile, no treatment is necessary

Encapsulated empyema occurs along the pleural surfaces, usually between the lobes of the lungs. The presence of an encapsulated empyema can be established only by roentgenologic examination and aspiration of the encapsulated pus

Complications of Empyema Infection of the thoracic wall is more likely to develop in those who have large abscess of the lung with profuse external discharge in the putrid type of empyema.

Empyema necessitatis is the spontaneous rupture of an empyema through the parietal pleura into the thoracic wall. Eventually the pus breaks through the skin This condition is rarely encountered except with tuberculous and actinomycotic infections.

A bronchopleural fistula may make its way to the surface of the thoracic wall,

the subsequent tuberculous empyema may be limited, but a mixed infection may develop later. Most of the patients in whom spontaneous pneumothorax develops in the course of tuberculosis become seriously ill. All of them have fever, and without exception a pleural exudate appears soon after the onset About half the patients die within one month, and probably fewer than 1 in every 10 regain health

EXAMINATION. On examination of a patient who has a pneumothorax, the affected side may be distended and nearly or absolutely immobile on respiration. The apex beat of the heart is displaced toward the normal side unless the mediastinum is immobile The vocal fremitus is enfeebled or absent. The trachea may be displaced toward the normal side. The percussion note is hyperresonant but it varies according to the tension of the gas in the pleural cavity. The affected side may be considered to be normal on percussion while the normal lung is thought to be the one affected On listening at the back of the thorax while someone else taps one coin on another in front, a distinct, metallic, echoing sound is heard. If there is a considerable amount of fluid or pus present in the thorax, the percussion dullness may be bounded by a horizontal line, and this line remains horizontal, irrespective of change in posture of the thorax. On shaking the patient, a metallic splashing sound may be audible. When a pulmonary fistula is patent, and is below the surface of the fluid in the pleural cavity, on the patient's lying down, or standing, the sound of gurgling fluid may be heard On auscultation over a pneumothorax the breath sounds may vary from markedly feeble to loud and amphoric.

DIAGNOSIS. If no abnormalities are found on physical examination, the roentgenologic examination will reveal the presence of pneumothorax. Fluid accumulates rapidly in the pneumothorax pocket It is important to determine whether the bronchopleural communication remains open, for if there is a widely open bronchopleural communication, withdrawal of large volumes of air does not alter the intrapleural pressure

The early management of these patients is concerned with removal of the pneumothorax air as needed In the mildest forms of the disease treatment may not be necessary.

Rheumatic Pleurisy. Rheumatic fever causes a small number of cases of serofibrinous pleurisy with effusion

Rheumatic fever attacks serous membranes selectively; for instance, the synovial membranes, the endocardium and the pericardium are common sites of rheumatic infection In a few cases the pleural membrane also is affected, with the production of a fibrinous pleurisy often quickly followed by serous pleural effusion. This sequence of events is particularly likely to occur in the presence of rheumatic *pneumonitis or pericarditis, whence the infection apparently spreads directly* or by extension along the lymphatics

Those who have rheumatic pleurisy have had rheumatic fever, and in all but a very few the pleural involvement occurs in the course of an acute exacerbation of symptoms The pleuritis may be preceded in onset by polyarthritis. However, in some patients the joints become involved after the onset of the pleurisy. The symptoms in this latter group of patients are those of rheumatic polyarthritis accompanied by the development of pleuritic pain Characteristically the patient is very ill, with high fever and dyspnea Rheumatic pleurisy often co-exists with pericarditis. Rarely a subacute or chronic rheumatic pleuritis is observed.

EXAMINATION. Early in the course of rheumatic pleurisy a pleural friction rub may be heard, but this is quickly superseded by signs of effusion In almost all of these patients examination by physical means reveals evidence of rheumatic mitral heart disease

A history of previous rheumatic fever or the presence of a rheumatic cardiac lesion is the chief clue in making a correct diagnosis. Rheumatic pleurisy is identified when a serous pleural effusion develops in the course of rheumatic fever. The

examination is made after thoracentesis. A definite diagnosis of tuberculous pleurisy is made by demonstration of the tubercle bacillus by inoculation of a guinea pig.

Histologic studies of the cells in the sediment should be made for presence of malignant cells

Tuberculous Empyema. Tuberculous empyema exists if the pleural exudate is definitely purulent and contains tubercle bacilli in sufficient numbers to be demonstrable in an unconcentrated smear. A tuberculous empyema is termed *simple* when the tubercle bacillus is the sole infecting organism, and *mixed* when in addition one or more other types of pathogenic bacteria are present in the pleural cavity.

1. ***Simple Tuberculous Empyema.*** The visceral and parietal pleura are considerably thickened by fibrous tissue together with caseous material. The pleural pus contains only tubercle bacilli, which are found by direct smear examination

Tuberculous pleural empyema may occur spontaneously, but often is present in those who have received artificial pneumothorax for pulmonary tuberculosis

The pathologic process is a subpleural tuberculous focus which has spread by caseation, liquefaction and rupture into the pleural cavity

At the onset of the empyema there is some fever, and often pain in the chest. The acute empyema may come on abruptly, usually soon after the induction of pneumothorax, owing to extensive pleural caseation In these instances the temperature rises rapidly to 104 F (40 C) and chills occur. Pleural pain in the involved side is an early symptom. The fever may persist for several weeks and subside gradually. Between these mild and severe attacks of the disease, gradations in severity of the clinical manifestations may exist.

The mortality rate in all cases of simple tuberculous empyema has been high, from 30 to 40 per cent

The diagnosis of simple tuberculous empyema is made when the presence of fluid in the pleural cavity is determined and aspiration yields a turbid or purulent exudate containing acid-fast bacilli on direct culture or smear, but giving sterile cultures for other bacteria.

2. ***Mixed Tuberculous Empyema.*** In the mixed tuberculous empyema the exudate is purulent and may contain a wide mixture of organisms

The pleural infection arises from a rupture of a caseous focus in the visceral pleura of a tuberculous lung, with the production of a bronchopleural fistula When such an event occurs, tubercle bacilli as well as the pyogenic flora of the bronchial tree reach the pleural cavity in large numbers

The symptoms of the mixed tuberculous empyema are the same as those of simple tuberculous empyema but more severe

The presence of a mixed infection may not be suspected until cultures of the pus reveal the pyogenic organisms The diagnosis of tuberculosis is suspected and proper isolation and care of the patient have been executed long before the presence of tubercle bacilli has been demonstrated by cultures

The prognosis is grave, more than 70 per cent mortality is to be expected

Tuberculous Spontaneous Pneumothorax. A region of tuberculous caseation originates in the subpleural tissues and extends to the pleural membrane, liquefies it and ruptures into the pleural space When rupture takes place, air, tubercle bacilli, and other microorganisms from the bronchial passages are admitted to the pleural cavity

SYMPTOMS. The patient, who is known to be suffering from pulmonary tuberculosis, has a sudden pain in the chest, becomes dyspneic and cyanotic and experiences varying degrees of shock In those who survive the initial episode, chills and fever ensue

In a few cases the pleural opening is small and closes rapidly. When this occurs,

which leave a moderate pleural fibrosis which persists. At times pleural effusions alone occur which are absorbed, leaving no evidence of their presence.

The findings on examination depend on the presence or absence of pneumonitis and pleural effusions.

Diagnosis depends on the status of the lung and pleura before roentgen therapy. If the examinations of the lung and pleura were recorded before roentgen therapy, and during the therapy if no other reason for the pleural changes occurred, it may be assumed that the pleurisy resulted from the irradiation therapy.

Traumatic Pneumothorax. Direct violence may cause pneumothorax by. (1) puncture of the lung by the sharp end of a fractured rib; (2) blows and crushing injuries without puncture of the thorax· in these injuries there are rupture of the visceral pleura, and intrapulmonary alveolar tears. The air then makes its way along the bronchovascular bundles to the hilus and reaches the mediastinum, causing mediastinal emphysema Secondary rupture of the mediastinal parietal pleura then produces pneumothorax; (3) penetrating wounds, and (4) artificial overinflation of the lung The use of excessive positive pressure in intratracheal anesthesia and pulmotors can produce pneumothorax.

In most of the instances caused by trauma the amount of air entering the pleural space is moderate or small. However, massive tension pneumothorax is occasionally seen.

SYMPTOMS. Often there is shock and this masks all other symptoms If there is no shock, pain in the injured side of the thorax is severe Dyspnea and cyanosis are severe if the pneumothorax is large In those who have small partial collapse, no symptoms in addition to those of the injury are observed

EXAMINATION Physical examination, in pneumothorax of moderate or large size, reveals hyperresonance to percussion which is often not great. The breath sounds are reduced or absent over the involved side of the thorax When a pneumothorax is extensive, the heart and trachea are frequently found to be displaced away from the side of the collapse. Signs of fluid in the pleural cavity are due to intrapleural blood from the site of injury Subcutaneous emphysema is a common occurrence in traumatic pneumothorax It usually develops when a break in continuity of the parietal pleura allows the escape of air from the pleural space which then makes its way to the subcutaneous tissue and may spread widely over the body. If extensive, subcutaneous emphysema is painful

DIAGNOSIS The presence of air in the pleural cavity is determined by the combined use of physical and roentgenologic methods The roentgenologic method is the only one by which the degree of collapse can be accurately determined

Chylothorax. Chylothorax consists of the accumulation of chyle in the pleural cavity This fluid has the appearance and stability of a solution of homogenized milk It contains varying amounts of fat (2 to 3 per cent) which are determined by the Babcock test as employed by dairymen

Injuries produced by hyperextension of the spinal column may rupture the thoracic duct After the injury a latent period of weeks may pass before fluid appears in the pleural cavity. The delay is due to retropleural accumulation of chyle. This chyloma appears as a mediastinal mass in the roentgenogram. The chyloma ruptures into the pleural space and chylothorax ensues. Chylothorax, like chyluria, may occur spontaneously.

Occasionally a mediastinal lymphosarcoma or Hodgkin's disease may completely obstruct and rupture the thoracic duct and produce chylothorax

The development of some instances of chylothorax is characteristic The onset of pleural pressure symptoms such as dyspnea, cyanosis, tachycardia, and a sense of tightness in the chest is severe Associated with these symptoms is a decline in weight, due to the loss of large amounts of digested and absorbed fat. In some instances the wasting and exhaustion of the patient continue to progress, and the

fluid removed by thoracentesis is an exudate which clots rapidly. It is sanguineous in appearance in more than half the cases. Leukocytes in the fluid number from 500 to 5,000 per cubic millimeter and a differential count usually shows a very slight preponderance of polymorphonuclear cells over lymphocytes. Cultures of the exudate are sterile. This condition must be differentiated from other pleurisies by the presence of other symptoms or signs of rheumatic disease.

PLEURISY DUE TO FILTRABLE VIRUSES

Epidemic Pleurodynia (Epidemic Myalgia). This disease is characterized by an acute febrile illness of brief duration whose chief symptom is severe thoracic pain indistinguishable from that of pleurisy. The disease has occurred in small sporadic epidemics, which usually are observed during the warm months of the year The incidence is chiefly among children and young adults.

From stored throat washings from those who had pleurodynia, Miller and associates of Harvard University and Tufts College recently isolated a virus antigenically related to the Connecticut 5 virus previously isolated by Melnick from a case of nonparalytic poliomyelitis

Epidemic pleurodynia has an abrupt onset with fever accompanied by a chill Pain on breathing or coughing appears simultaneously and is limited to the lower intercostal regions of one side. However, instances with bilateral pain, headache, abdominal pains and stiffness of the back and neck have been recorded

The temperature reaches 101 to 104 F (38.3 to 40 C) and the fever and pain persist, as a rule, for 12 to 48 hours Thereafter the symptoms subside rather rapidly, but after an interval of 2 days or so about one fifth of the patients have a second paroxysm of pain and fever identical in character with the first, but usually somewhat less severe. After this, recovery is prompt, there being no complications Death from epidemic pleurodynia has never been reported

Examination often reveals that the patient has a moderately red throat, but cough is not common. The involved side of the thorax may reveal muscle guarding and there is tenderness on pressure in the intercostal spaces over the painful region Pleural friction rubs on auscultation are inconstantly present.

DIAGNOSIS. The course of the disease and its occurrence as part of an epidemic must decide the diagnosis. It would be impossible to identify a sporadic case of epidemic pleurodynia Leukocyte counts reveal a mild leukopenia during the active stage of the disease

DISEASES OF THE PLEURA DUE TO TRAUMA OR PHYSICAL AGENT

Traumatic Serofibrinous Pleurisy. *Serofibrinous pleurisy* may develop as a sequel of direct trauma to the thorax In general it appears that the serofibrinous pleurisy most commonly is associated with a subpleural hematoma The common causes of serofibrinous pleurisy are fractures of ribs with the formation of hematoma subpleurally at the site of the fracture, with or without actual penetration of the parietal pleura by the fractured fragments of bone However, hematomas may occur from contusion of the thoracic wall without rib fracture. Likewise contusion of a lung, due to either direct or contrecoup violence, with hematoma beneath the visceral pleura, may be associated with serofibrinous pleurisy It seems that the size of the effusion is ordinarily small and the fluid is blood stained. Cultures of these effusions are sterile unless secondarily infected by pyogenic bacteria

Pleurisy Following Irradiation Therapy. After intensive roentgen therapy to the thorax a pulmonary reaction may occur. In the beginning there is the appearance of a pneumonitis which progresses slowly, resolves slowly, and heals poorly, for sometimes there is left an increase in fibrous tissue in the involved region of the lung In some cases of this roentgen pneumonitis, changes develop in the pleura

Pleural Transudates. ***Venous Passive Congestion.*** The usual cause of passive congestion in the veins draining the visceral and parietal pleura is congestive cardiac failure. Constrictive pericarditis has a somewhat similar effect In the occasional case of obstruction of the superior vena cava, congestion of the parietal pleura develops because of interference with return flow through the azygos system.

The symptoms are those of congestive heart failure. The findings on examination by physical means are those of heart failure and fluid in the pleural space, especially on the right side of the thorax.

The fluid obtained by thoracentesis is a thin straw-colored fluid, relatively clear, and having a specific gravity usually less than 1.014. If the effusion has been present for some time, reabsorption of water may cause concentration of the proteins, giving a higher specific gravity. In uncomplicated cases the fluid contains very few cells, usually less than 500 per cubic millimeter, and these are lymphocytes. The presence of polymorphonuclear leukocytes and erythrocytes suggests the existence of a complicating pulmonary infarct or a secondary infection of the transudate, an empyema. An empyema in a patient who has heart failure is suggestive of a dispersion of infected thrombi from a bacterial endocarditis.

PLEURISY OF ENDOCRINE ORIGIN
(*Meigs' Syndrome*)

In the presence of benign fibroma of the ovary there may be associated a sterile serous pleural effusion and serous ascites. Women between the ages of 30 and 65 years complain of dyspnea and unilateral thoracic pain. There is no fever. Examination reveals physical signs of pleural effusion the presence of which is confirmed by the roentgenogram The ovarian fibroma is variable in size but can ordinarily be detected on pelvic examination

Thoracentesis yields a thin straw-colored fluid, which contains but few leukocytes—usually fewer than 1,000 per cubic millimeter—the majority of which are lymphocytes Cultures and inoculation of guinea pigs with the fluid are negative. Results of examination for neoplastic cells are negative.

The diagnosis is confirmed by the finding of fibroma of the ovary in the absence of heart failure or embolism A patient who is found to have an ovarian tumor with pleural effusion, everything else being negative for positive evidence of malignant disease, should have the pelvis surgically explored if there be an enlargement of an ovary Patients afflicted with Meigs' syndrome have recovered completely after removal of the ovarian fibroma.

SPONTANEOUS PNEUMOTHORAX

The term spontaneous pneumothorax implies that air has spontaneously entered the pleural space and thus produced a collapse of the lung Spontaneous pneumothorax despite its cognomen in the series of pneumothoraces usually results from rupture of an emphysematous bulla, situated on the surface of the lung, into the pleural space

The normally existing negative intrapleural pressure is an expression of the physiologic internal elasticity of the lung which brings it to a smaller volume while at rest. The lung remains expanded because of its internal atmospheric pressure, which is a greater force than this normal force of contractility of the lung When a communication develops between the pleural space and the atmosphere through an opening in the

equalize itself with

acts the lung to a

...nitted to enter the

pleural cavity to compensate for the shrinkage, and pneumothorax results In an otherwise normal thorax the difference in pressure between the two pleural cavities causes a displacement of the mediastinal structures away from the side of the pneumothorax

condition is fatal within a few weeks. In other cases, after the initial accumulation of pleural fluid, the mediastinal pressure becomes stabilized so that pressure symptoms are no longer severe The pressure appears to reduce the leakage of the fluid into the pleural sac.

Some patients carry a large chylothorax and enjoy fairly good health However, most of those who have chylothorax die within a period of a few months.

Physical and roentgenologic signs are those of pleural effusion. The presence of chylothorax is established by thoracentesis. Aspiration yields a fluid having the appearance of milk. The Babcock test for fat reveals a fat content of from 1 to 2 per cent or more, which establishes the diagnosis

Hemothorax. In hemothorax the pleural cavity contains blood, little if at all diluted with serous exudate Hemothorax originates from many causes, trauma and malignant disease are the common agents.

After an intrapleural hemorrhage has taken place, the blood gradually undergoes a change in color (conversion of hemoglobin to bilirubin). If the blood withdrawn by thoracentesis is centrifuged, a yellow or brownish tinge in the supernatant plasma indicates that bilirubin has already been formed and therefore the hemorrhage must have begun at least a day or two or longer prior to the aspiration.

Hemopneumothorax. Hemopneumothorax is the combined presence of blood and air in the pleural cavity This condition is most frequently the sequela of traumatic pneumothorax, and the blood comes from an intrapleural wound

Hemopneumothorax, however, occasionally occurs in idiopathic pneumothorax, and more rarely in the tuberculous and emphysematous types of spontaneous pneumothorax If the amount of blood in the thorax is small, it will not affect the course of the pneumothorax.

A low-grade fever may be produced by pleural irritation and disintegration of blood In the rare instances in which severe hemorrhage has occurred, shock may ensue.

Except in those known to have tuberculosis, hemopneumothorax is suspected when a sizable effusion appears in the pleural cavity of a person who has a pneumothorax Aspiration of some of the fluid confirms the diagnosis

The blood is removed from the pleural space to prevent future fibrosis and calcification.

PLEURAL EFFUSIONS SECONDARY TO DISORDERS OF CIRCULATION

These effusions are usually sterile like those from the pneumococcus and rheumatic pleurisies Pneumococcal empyema occurs in those who have had untreated lobar pneumonia.

Pleural Effusion Due to Pulmonary Infarction. The occurrence of a pulmonary infarct is followed by an intense inflammation-like reaction of the pleura when the infarct is situated near the periphery of the lung. A thin layer of fibrinous exudate rapidly appears on the visceral pleura overlying the infarct Then a serous exudate begins to accumulate in the pleural space, the fluid developing rapidly and commonly becoming sanguineous from leakage of erythrocytes from the intensely congested infarcted tissue

Immediately after the infarct there may be no signs of pleurisy on examination by physical means Twelve to 24 hours after the accident a pleural rub, and later the signs of pleural effusion, will be present in all subpleural infarctions

The diagnosis is established by roentgenoscopic examination In case the pleural exudate is examined, it will reveal a leukocyte count in the fluid of 1,000 cells per cubic millimeter or less The fluid is sterile on culture and contains no tumor cells, and tubercle bacilli cannot be recovered by guinea pig inoculation

PLEURAL THICKENING

During the routine examinations of the thorax there may not be signs of pleural thickening Roentgenologic examination may, however, reveal some thickening of the pleura. These pleural thickenings are of varying degrees and extent. A chronic inflammation of the pleura with formation of new fibrous tissue, and with adhesions between two layers, in rare instances may extend to the point of obliteration of the whole pleural cavity on one side, with retraction of the thorax. The side of the thorax which is affected is shorter than the other. There is scoliosis with concavity toward the shrunken side. The shoulder on the affected side is depressed and the intercostal spaces are narrowed. There are diminished expansion, dullness on percussion, and enfeeblement of the breath and voice sounds and of vocal fremitus Litten's phenomenon is absent. As the side becomes shrunken, the mediastinum and the heart are drawn toward it If there be much thickening, an exploratory needle may have to be jabbed through a thick layer of tough, fibrous tissue In some instances of this type of pleurisy the whole pleura becomes calcified Adhesions to the diaphragm are often exquisitely demonstrated on roentgenographic examination

Commonly, however, there will be observed circumscribed adhesions only, usually to the diaphragm or at the bases of the lungs The etiology of these pleural thickenings is not known Great thickenings of the pleura are most often due to tuberculous pleurisy

If signs and symptoms of this type of pleurisy are present, they usually are minimal. At times, however, the patients may be slightly cyanotic, and they often have some dyspnea on exertion

MALIGNANT TUMORS OF THE PLEURA

Primary Malignant Lesions. The pathologists have complained of the difficulty in the histologic classification of primary pleural malignant tumors. These tumors may be called carcinomas, sarcomas, endotheliomas and mesotheliomas The manifestations of these tumors are not distinctive nor can the neoplasms be definitely separated from secondary metastatic malignant lesions

The metastatic tumors which involve the pleura are mostly carcinomas and sarcomas

The first symptom of pleural tumors is heaviness or fullness in the thorax, often a dull, aching sensation. Soon pain is associated with respiration, and it is sharp and cutting in nature Dyspnea, shortness of breath, cough, expectoration and loss of weight and strength follow in rapid sequence.

Fever, palpitation and tachycardia are common The evidence of cardiac embarrassment through mediastinal compression which may ensue is the presence of edèma of the extremities and ascites Ptosis, enophthalmus and contracted pupil (Horner's syndrome) may result from pressure on autonomic nerves.

In some instances on examination there is a tumor of the thoracic wall Decreased expansion of the thorax, edema of the arms and legs, abdominal ascites, engorgement of vessels of the thoracic wall and edema may have developed as a result of mediastinal compression and encroachment on the heart or large blood vessels

On percussion of the thorax either dullness or flatness will be elicited over irregular regions Often the neoplasm is diffuse or, if there is fluid in the pleural cavity, dullness and flatness may be extensive A high diaphragm on the side of the lesion usually can be elicited by physical means and indicates direct diaphragmatic or phrenic nerve involvement Auscultatory findings consist of diminished or absent breath sounds Rarely will there be rales, and pleural friction rubs are unlikely.

Occasionally, as a lung collapses, the consequent contraction of the pleural membrane will close the bronchopleural opening and thus halt the process at this point. The normal pressure relationships are somewhat re-established and the intrapleural pressure remains slightly negative as compared to the atmosphere.

The term tension pneumothorax indicates the building up of an intrapleural pressure greater than atmospheric pressure This serious condition is permitted to develop by a bronchopleural communication, a one-way valve action which allows air to pass only from the lung to the pleural space (Meyers).

Pulmonary Emphysematous Spontaneous Pneumothorax. In pulmonary emphysema there are often subpleural bullae containing air and communicating with the bronchial tree The visceral pleura is the outer wall of the blebs. Rupture of one of these subpleural bullae produces spontaneous pneumothorax. In these instances collapse of the lung is only partial. In cases of tension pneumothorax the increased intrapleural pressure is great enough to collapse even an emphysematous lung.

The patient who has emphysema suffers from severe pleuritic pain in one side. Dyspnea and cyanosis are evident except in the mildest instances of pneumothorax and vary in degree with the extent of the collapse Fever is uncommon and pleural effusion usually does not occur.

Physical examination reveals the signs of pneumothorax on the side of the pain When subcutaneous emphysema appears, it is ordinarily secondary to mediastinal emphysema; hence the presence of air is first observed in the tissues of the neck, from which it may spread. The diagnosis is established by the finding, on physical and roentgenologic examination, of pneumothorax in a patient suffering from pulmonary emphysema.

Spontaneous pneumothorax due to emphysema often recurs. There being no pleural inflammation at the time of the collapse, adhesions frequently do not form and the same or a different emphysematous bleb may rupture again In some instances multiple recurrences have been observed In a patient who has extensive emphysema, severe spontaneous pneumothorax may be fatal.

Idiopathic Spontaneous Pneumothorax. The term idiopathic pneumothorax is aptly applied because in the rare fatal instances of the disease necropsy has not disclosed a bleb or the point of pleural rupture. If a pleural rupture is demonstrated, it is the so-called subpleural vesicle, a local congenital weakness of the pleural tissues.

Idiopathic pneumothorax occurs in young, healthy adults The onset is with a sudden violent pain in one side of the thorax There may be shock The respirations are shallow and rapid The patient may have a slight fever for 2 or 3 days but none thereafter, and in many cases the temperature remains normal throughout

Physical examination reveals signs of pneumothorax on the side of the pain and, in marked instances, some degree of mediastinal displacement away from the side of the lesion

In idiopathic benign spontaneous pneumothorax, pleural fluid usually does not appear. In some instances a small amount of serous exudate develops If a large pleural effusion is found, the most likely cause is hemothorax, as a result of bleeding from the lung at the time of pleural rupture

Subcutaneous emphysema occurs occasionally in idiopathic spontaneous pneumothorax The subcutaneous air appears first in the neck and subsequently spreads

A diagnosis of idiopathic spontaneous pneumothorax is justified when the condition develops in the absence of trauma in a young patient who has no known preexisting pulmonary disease. A roentgenologic examination reveals and confirms the presence of a pneumothorax. The extent of a pneumothorax can be determined only by roentgenologic investigation.

in bed The pain is situated in the region of the epigastrium or just above the ensiform cartilage. The symptoms may be suggestive of gallbladder disease, ulcer, or *angina pectoris*.

The findings on physical examination depend on how large the hernia may be. If the hernia is large, there is thoracic tympany, and borborygmi are heard in parts of the thorax usually occupied by the lungs. In small hernias there are no signs on examination

The hernia is revealed by roentgenoscopic examination after the patient has ingested a barium meal In large hernias the diagnosis may be suspected from physical examination or the history or may be found on a routine roentgenogram of the chest.

When diaphragmatic hernias are discovered accidentally and are not causing symptoms, no treatment is necessary.

False Hernia. The false diaphragmatic hernias are always due to an arrest of development of the pleuroperitoneal membrane with a congenital absence of a part of the diaphragm Congenital defects of this kind occur much more frequently on the left side than on the right An absence of a part of the left half of the diaphragm permits the abdominal organs, such as the stomach and parts of the intestine and occasionally the spleen, the pancreas and the left kidney, as well as a portion of the liver, to enter the perforated pleural cavity In the extremes, most of the pleural cavity is occupied by these organs Such hernias vary in extent from this extreme to those with defects in the diaphragm which admit only small parts of the abdominal contents.

The symptoms are variable in degree and often none are present.

In extreme instances of diaphragmatic hernia, tympany on percussion and peristaltic sounds on auscultation on examination of the thorax are diagnostic. In those hernias which admit only a small portion of an abdominal viscus into the pleural cavity, the diagnosis is established by roentgenoscopic inspection after the patient has ingested a barium meal.

INFECTIONS OF THE DIAPHRAGM

Acute Diaphragmatitis. Acute diaphragmatitis is usually associated with acute infections situated either in the thorax or in the abdomen such as pneumonia and peritonitis, or with general disease of the body as a whole In other instances of acute diaphragmatitis the etiology is usually not known

There is an acute inflammation, with swelling of the muscle fibers, which may be limited to the muscle or may extend to its serous coverings Fluid may accumulate, followed by adhesions and obliteration of the cardiophrenic and costophrenic angles These inflammatory processes may destroy muscle, which is replaced by fibrous tissues, and thus the diaphragm partially loses its ability to function and appears flat rather than dome-shaped on roentgenoscopic examination

The disease may extend, however, so as to involve the diaphragmatic pleura, resulting in pleural effusion and even empyema. It may then extend to the visceral pleura, to the diaphragmatic peritoneum, and to the liver, and thus produce symptoms indicating the extension of the disease

The symptoms commence with a chill and fever followed by pain over the costal margins and in the shoulder region of the involved side. Often there are pain and soreness across the upper part of the abdomen The pain is intensified on inspiration and change in posture The symptoms are often very much like those of a pneumonia which affects the base of the lung or both lungs

The symptoms disappear within a few days but often recur at irregular intervals. Unless the lung is affected, there are little or no cough and expectoration There are often a loss of body weight, anorexia and constipation

The patient on examination may or may not appear ill. Limitation of motion or a partial immobilization of the diaphragm and the lower part of the thoracic

For practical purposes roentgenologic examination often sufficiently limits the diagnostic possibilities. The diagnosis as to the type of tumor is established by microscopic study. Malignant cells may be *demonstrated in the bloody pleural* fluid obtained on aspiration.

DISEASES OF THE DIAPHRAGM

Position of Diaphragm. The peripheral projection of the diaphragm adheres closely to the lower borders of the lungs (see pp 536 and 537).

The *diaphragm is elevated* by peritoneal fluid or air, or gas in the digestive tract; tumors, or pregnancy, conditions within the thorax, such as atelectasis, extensive pulmonary fibrosis and adhesions; interruption of a phrenic nerve; congenital muscular defects and myasthenia gravis.

The diaphragm may occupy a *low position* in acute diaphragmatitis; phrenic nerve irritation, as may occur in encephalitis, tetanus, tetany and singultus with peritonitis; visceroptosis and asthenias, pleural fluid, pneumothorax, emphysema, asthma and intrathoracic tumors.

The diaphragmatic muscle may be involved by acute infections. The pleural surfaces of the diaphragm often participate in the infections or malignant lesions of the rest of the pleural surfaces of the thorax. The peritoneal surface likewise participates in the malignant disease and infections of the peritoneal cavity.

DISEASES OF THE DIAPHRAGM DUE TO PRENATAL INFLUENCES

Congenital Eventration of the Diaphragm. *This condition* is called also elevation, dilatation, high position, insufficiency, relaxation of the diaphragm, and Petit's disease

Eventration of the diaphragm is often due to a congenital fault, which is a failure of the diaphragmatic musculature to develop on one side, usually the left side. In place of the muscle there exists only a thin membrane The pleural and peritoneal components are intact, but in the absence of muscle *the involved part* of the diaphragm yields to pressure.

The condition is characterized by an abnormally high position of one half of the diaphragm The high position is permanent and the diaphragm is intact The abdominal viscera are placed high and occupy space which topographically belongs in the thoracic cavity

There may be dyspnea, substernal pain, discomfort or pain after meals, and occasionally nausea and vomiting. Usually, however, there are no symptoms

On examination an increase in the respiratory expansion of the thorax in the region of the costal margins may be observed while the patient stands. This increase in inspiratory expansion is made less obvious when the patient is in the recumbent posture. Tympany may be elicited over the lower part of the thorax which is normally occupied by lung Borborygmi may be heard over the lower part of the thorax in positions where these sounds are not normally audible.

The diagnosis is established by roentgenoscopic study after the patient has ingested a barium meal.

In most cases of eventration of the diaphragm no treatment is necessary

Congenital Diaphragmatic Hernia. Congenital diaphragmatic hernias are separated on an anatomic basis as true hernias and false hernias

True Hernia. In a true diaphragmatic hernia the abdominal contents extend through the diaphragm into the thorax within the sac formed by the serous coverings of the diaphragm These hernias occur most frequently at the esophageal foramen. However, they may occur in any part of the diaphragm. They often result from congenital imperfections in the diaphragmatic muscle

Often there are no symptoms. In most instances of diaphragmatic *hernia, however*, pain is present when the stomach is full and often while th- patient is lying

Secondary Diaphragmatitis. Pneumonia and peritonitis are common causes of secondary diaphragmatitis In basal lobar pneumonia marked diaphragmatic changes occur, and in fatal instances of the disease the postmortem examinations often reveal waxy degeneration of the muscle fibers. In cases of bronchial pneumonia the diaphragmatic changes are slight and recovery is often complete.

[illegible]

exu[illegible]

mos[illegible]

itself.

The weight of pleural effusion damages the diaphragm by producing stretching deformity and loss of elasticity. When fluid is present in the pleural space, there is a tendency for adhesions to form in the costophrenic angles and between the pericardium and the diaphragm, fixing the diaphragm in an abnormal position which impairs its function In cases of extreme diaphragmatic adhesions the heart may be displaced

In any chronic infection of the lung when dyspnea is out of proportion to the amount of pulmonary involvement, an impairment of diaphragmatic function is suspected as being at least partially responsible. In tuberculosis and pneumoconiosis bilateral diaphragmatic adhesions may result in marked restriction of the diaphragmatic excursion and thus dyspnea is inevitable.

SUBDIAPHRAGMATIC ABSCESS

Subdiaphragmatic or subphrenic abscess is a collection of pus beneath the diaphragm It is usually subsequent to some suppurative process within the abdomen Other causes, however, have included infection carried from some distant focus by the blood or lymph and invasion of the subphrenic space by extension through the diaphragm of a suppurative process within the thorax.

*The subphrenic portion of the body extends from the diaphragm to the trans*verse colon This region is subdivided by the liver and the arrangements of its peritoneal folds or ligaments, to form three subphrenic spaces on the right side and one space on the left

Location of Abscess The right side is more frequently involved than the left because the most frequent diseases preceding subphrenic abscess are lesions of the appendix, gallbladder and duodenum. There are occasions, however, when these lesions are followed by subphrenic abscess on the left side.

The microorganisms found on culture from subdiaphragmatic abscesses are, in the order of frequency, streptococci, gram-negative bacilli, staphylococci, *Escherichia coli,* Proteus and various micrococci

Symptoms The symptoms of subphrenic abscess depend on the combination of many variable factors and are therefore largely dependent on the symptoms *of the original lesion or on the postoperative discomforts incident* to a recent operative procedure These discomforts may accentuate, diminish, or completely mask the symptoms produced by the subphrenic abscess. The particular subphrenic space involved by the abscess, the onset of the disease, the general condition of the patient, the presence or absence of complications, and the nature of those complications present will influence the symptoms. The symptoms may be summarized as general reactions, local reactions and pleural reactions

The general reaction often is that of overwhelming infection. The onset is *sudden with fever, chill and fever* and the patient is seriously ill When the infection becomes localized, there is pain situated in the region of the diaphragm and the findings may simulate a pleurisy.

The pleural and local manifestations revealed by physical examination are often meager indeed despite the presence of intense pain with high fever. However, in some there is evidence of pleural effusion or pneumonia.

wall may be observed. In the beginning there are no abnormal auscultatory findings. *There is no descent of the diaphragm on inspiration.* A pleural effusion may be present.

As the disease develops and the diaphragm becomes immobile, there may be congestion at the bases of the lungs. Spasm of the transversus abdominis muscle is observed on palpation. Spasm of the muscle may be due to extension of the inflammatory condition into the fibers of muscle. The polymorphonuclear leukocytes range from 9,000 to 20,000 per cubic millimeter of blood after the symptoms are well established

The diagnosis of diaphragmatitis is suggested by the history and immobility of the diaphragm, determined by physical signs and by roentgenoscopic examination, with pain over the apex of the shoulder.

Diaphragmatitis must be differentiated from spontaneous pneumothorax, artificial or spontaneous pneumoperitoneum, acute conditions of the abdomen which extend to the diaphragm or the transversus abdominis muscle, intercostal herpes zoster, pleurodynia, acute spasm of the diaphragm, irritation of the phrenic nerve in the mediastinum, basal pneumonitis, scalenus syndrome, and cervical ribs.

There is no specific treatment for this condition.

Epidemic Hiccough (Devil's Grippe). Epidemic hiccough has been observed in rural communities The consensus is that the disease is due to an infection of viral origin. The causative organism is unknown. The infection apparently spreads through families by contact.

The onset is sudden, with epigastric and thoracic pain and increased respiratory rate. *Respiration may be difficult, and in some cases the rate is as high as 60 per minute* From the onset there is often a fever, with the temperature from 101 to 105 F (38.3 to 40 5 C). Profuse perspiration is the rule There may be nausea and vomiting in the early stages of the disease. After about 4 hours of severe paroxysms of pain and dyspnea the symptoms subside. In no case do severe symptoms persist more than 24 hours without relief After 3 or 4 days from the onset *there may be* diarrhea.

Examination of those who have paroxysms of abdominal pain may reveal muscle guarding and splinting In all others the presence of hiccough is the only positive finding

The diagnosis in a sporadic instance of the disease cannot be made. Diagnosis is established during an epidemic mainly by the short duration of the hiccough, fever and the presence of other cases in the community.

The differentiation of hiccough from diaphragmatic tic is made on the rate of diaphragmatic activity *Hiccough may occur at rates of from 10 to 20 times per minute.* In the diaphragmatic tic or spasm which follows encephalitis the contractures occur from 60 to 200 times per minute. In diaphragmatic tic roentgenoscopic inspection of the diaphragm reveals these contractions with no other movement. On forced respiration, however, the diaphragm is seen to descend and ascend while the small, rapid contractions continue. In some cases temporary or *permanent* interruption of the phrenic nerve has been necessary.

In ordinary hiccough no effective treatment is known which deserves mention. Inhalation of oxygen and carbon dioxide, if administered by the use of a mask, prevents the patient from uttering audible complaints.

Trichinella Spiralis. *Trichinella*, a genus of the nematode parasites of the family Trichinellidae, causes the disease trichinosis, and may cause a primary diaphragmatitis. The organisms enter the diaphragm, as is true of other muscles of the body, and may produce serious myositis Indeed, the involvement, together with that of the intercostal muscles, may become so *extensive as to cause death* (see Intestinal Parasites, Chapter 13).

bowel, the mortality is high immediately following the accident. After the acute injury has improved surgical operation may not be immediately urgent.

DISEASES OF THE DIAPHRAGM SECONDARY TO DISTURBANCES OF INNERVATION OR PSYCHIC CONTROL

Paralysis of the Diaphragm. Unilateral or bilateral paralysis of the diaphragm may be caused by hemorrhages, poliomyelitis, and tumors involving the spinal cord or the phrenic nerve Injuries or operations on the neck may crush or disrupt the phrenic nerve and thus result in temporary or permanent diaphragmatic paralysis on the same side Injury of the brachial plexus may cause paralysis of the diaphragm A tuberculous process or malignant lymphoma adjacent to the phrenic *nerve, as it courses through the thorax, may involve it so as to result in paralysis* of the diaphragm.

When the entire diaphragm is paralyzed, excitement or exertion results in marked dyspnea In unilateral paralysis symptoms are meager or absent In those who have extensive adhesions in the upper part of the abdomen, severe motor symptoms referable to the intestines may follow interruption of the phrenic nerve, and subsequent diaphragmatic paralysis may develop, particularly when the interruption is of the left phrenic nerve

On examination in some instances visible paradoxical movements of the diaphragm are observed When one side of the diaphragm moves downward while the other side moves upward on inspiration, paralysis is suspected.

In most instances the diagnosis is made by roentgenoscopic examination

There is no treatment capable of restoring the function of the paralyzed diaphragm

Spasm of the Diaphragm (Hiccough, Hiccup, Singultus). Hiccough is a sudden contraction of the diaphragm. If the mouth is not kept closed during the singultus, a sound is produced by the quick closure of the glottis Hiccough is often produced by the swallowing of dry food without sufficient drink It is a common postoperative complication, perhaps from an irritation within the abdomen It is an ominous symptom in general peritonitis Pleuritis or pericarditis may cause hiccough Involvement of the phrenic nerve anywhere along its course is a common cause of hiccough Tumors in the medulla, encephalitis, injuries to the phrenic nerve from wounds and trauma, pressure from tumors in the neck or thorax, disease of the meninges or vertebrae in the region of the third and fourth thoracic roots, peripheral neuritis, lead poisoning involving the phrenic nerve, and inflammation of the terminal fibers within the diaphragm may result in hiccough Epidemic hiccough is thought to be associated with encephalitis Sometimes hiccough is a hysterical manifestation

The onset is sudden regardless of the cause There may be only a few contractions of the diaphragm, after which the condition completely disappears When hiccough persists, pain and soreness may be experienced over the attachments of the diaphragm to the thoracic wall and of the muscles of the thorax and abdomen

Hiccough usually is a simple and harmless condition However, if it persists, it may lead to exhaustion and to death. When the diaphragm becomes weak from prolonged hiccough, the bases of the lungs do not fill well with air on inspiration, and congestion results The dangers of bronchitis and pneumonia are then obvious. When prolonged hiccough occurs in persons suffering from terminal diseases, it often indicates that death is near

The diagnosis of hiccough is obvious. A diagnosis of the cause of the symptom hiccough is often impossible. The usual types clear spontaneously.

Diaphragmatic Flutter. Irregular clonic spasm of the diaphragm, or hiccough, is a common disorder in health, and its significance in disease is variable Tonic spasm of the diaphragm is seen in chronic form in emphysematous patients and

Any abdominal suppurative process or abdominal operation followed by an unsatisfactory postoperative course which is characterized by chills, fever, pleural pain and effusion, and unilateral elevation of the diaphragm arouses suspicion of the possibility of a subphrenic abscess.

The most dependable roentgenologic evidence indicative of subphrenic abscess are evidences of pleural effusion and elevated diaphragm. These roentgenologic findings are not conclusive, but *in correlation with the history and the other findings* they are strongly suggestive of subphrenic abscess. In some cases the roentgenologic findings are negative Early diagnosis of subphrenic abscess is usually dependent on a suspicion of its presence Once the diagnosis is suspected, the institution of proper treatment depends on localizing the lesion as accurately as possible to determine the most satisfactory approach for surgical exploration

DISEASES OF THE DIAPHRAGM DUE TO TRAUMA

Traumatic Eventration of the Diaphragm. Traumatic eventration of the diaphragm is designated also traumatic hernia, false hernia and hernia spuria

Eventration of the diaphragm results from a tear in the diaphragm Such tears often are sustained *from blows to the lower part of the thorax or the upper part* of the abdomen; accidents which result in crushing of the thorax, gunshot or stab wounds, or extreme straining In some cases of injury only the muscle is affected, and the peritoneal and pleural coverings of the diaphragm remain intact. Thus, when the abdominal contents enter the thorax, they carry with them the sac and may be considered as true hernias. In other cases the rupture is complete, whereupon the abdominal contents pass into the thorax without a sac The size of the tear determines the degree and severity of the hernia A small rent may become enlarged through pressure on the abdomen or through extreme contraction of the abdominal muscles as in straining As in congenital diaphragmatic hernia, eventration occurs most frequently on the left side However, both right-sided and left-sided rents in the diaphragm occur. When a tear is situated on the right side, a part of the liver itself may extend through the opening

Immediate death may result from the diaphragmatic eventration In the usual patient, however, the initial symptoms have commenced with nausea, vomiting, pain, dyspnea and hiccough. As the patient recovers from the acute illness he has pain in the thorax, often simulating angina pectoris, gallbladder colic or vague chronic digestive disorders The pain, belching and feeling of fullness in the thorax are worse after meals and particularly on retiring at night when the stomach is full

On examination and on inspection soon after the accident, if a large volume of the abdominal contents has entered the thorax, the abdomen appears flat and there may be evidence of recent trauma such as a puncture wound or crushing injury. Movements of the thoracic wall on respiration are markedly restricted

Palpation discloses that the movements of the thoracic wall are markedly decreased or absent on the involved side. Tactile fremitus cannot be elicited and the heart may be displaced toward the contralateral side. The percussion note depends on which part of the abdominal contents has entered the thorax If the spleen has entered or if blood has accumulated, a flat note is elicited If the stomach and intestines are present, a tympanitic note may be heard On auscultation, because of the collapsed or compressed lung, breath sounds are absent and the sounds due to air and fluid in the stomach and intestines usually heard over the abdomen may now be elicited over the thorax After recovery from the immediate effects of the accident examination by physical means may be negative.

Roentgenologic examination after ingestion of a barium meal reveals evidence of parts of the *gastrointestinal organs in the thorax*

Immediate surgical operation may be indicated for the acute injury. Pleurisy and peritonitis are always possible complications Because of shock and strangulated

increase in voice sounds Abscesses in the posterior mediastinum sometimes rupture into the trachea or bronchi, the esophagus or pleural cavity. Occasionally they appear in a posterior triangle of the neck. Those which extend into the retroperitoneal space may manifest themselves in the groin

Abscesses in the posterior mediastinum may disappear soon after drainage is established through rupture into the esophagus, the trachea or a bronchus.

The diagnosis is seldom made until rupture occurs. However, if the condition is suspected, the ingestion of barium sulfate by the patient enables visualization of the esophagus displaced ventrally Often there is evidence of obstruction due to pressure. Abscesses in other mediastinal parts, if they should occur, are not diagnosable

MEDIASTINAL EMPHYSEMA

Air in the mediastinum may follow severe coughing, crying, lifting, straining at stool, thoracic injuries, overdistention of the lungs, surgical procedures on the lungs and pleura, the use of positive-pressure anesthesia, spontaneous interstitial pulmonary emphysema, pulmonary diseases such as bronchopneumonia, influenza, asthma and tuberculosis, and a ruptured abdominal viscus

On reaching the mediastinum, air travels along courses of least resistance toward the cervical, occasionally toward the abdominal regions In the neck air localizes in the subcutaneous tissues where it is detected by means of the crepitations elicited on palpation The air reaching the retroperitoneal space may rupture through the peritoneum and result in pneumoperitoneum, or it may course downward through the inguinal rings, causing subcutaneous emphysema of the thighs and abdominal wall Air in the peritoneal cavity, when there is no rupture of an abdominal viscus, usually arrives there from the lungs

Symptoms. Often the escape of air into the retroperitoneal space and into the region of the neck is accomplished with but mild discomfort However, if air reaches the mediastinum under high pressure, as for instance from a high pressure pneumothorax, the pain is excruciating The pain may extend to the left shoulder and the left arm There is a sense of pressure beneath the sternum Swallowing and turning the head are painful There are severe dyspnea and cyanosis When the intramediastinal pressure approaches zero, the return flow of blood to the auricles is lessened through compression of the systemic and pulmonary veins

Examination There is often swelling of the cervical region when the subcutaneous emphysema is marked The presence of swelling over the abdomen, the inguinal region, and the thighs may signify subcutaneous emphysema in these regions

A subcutaneous emphysema is characterized by crepitations on palpation of the subcutaneous tissue When considerable air has accumulated in the mediastinum, the percussion note over the sternum becomes hyperresonant On auscultation, crackling, popping sounds are heard over the sternum and over the surface of the neck and along its borders which are increased when the heart is in systole

Diagnosis The physical findings are diagnostic. In instances in which diagnostic uncertainties prevail, lateral roentgenograms may be very helpful

Usually the prognosis is excellent. In most cases of mediastinal emphysema treatment is not required

In instances of acute mediastinal emphysema the syndrome of acute coronary occlusion may be simulated A short period of observation plus electrocardiographic studies will identify the condition present.

TUMORS OF THE MEDIASTINUM

Infections may reach the mediastinal lymph nodes from the neck, the abdomen, the lungs and pleura and the surface of the thorax and cause them to enlarge. The tubercle bacillus is the chief cause of the enlargement, but other agents also, such

cannot be made by any means of examination. It is suspected if the infection extends to the neck or downward into the retroperitoneal tissues or into the hili of the lungs

Acute Mediastinal Abscess. The etiology of acute mediastinal abscesses is the same as that of acute mediastinitis. Abscesses in the anterior mediastinum are caused by extensions of infection from lymph nodes, and by erysipelas, and occur after operations on the lungs, the larynx, the neck and the sternum. Occasionally a mediastinal abscess is a complication of disease in the abdomen, for instance, a gallbladder infection, and particularly perforation of the gallbladder.

There is moderate fever, and pain and throbbing are present beneath the sternum. The pain is accentuated by movements of the trachea, as by coughing.

On examination, often the veins of the neck are distended. There are swelling and edema of the neck and thoracic wall Increased percussion dullness is often elicited over the manubrium Leukocytosis is present.

The diagnosis may be obvious from the foregoing physical findings in association with roentgenologic evidence of a mass displacing the trachea. At times, if there should be only miliary abscess, the diagnosis may not even be suspected clinically.

Chronic Mediastinitis. Chronic mediastinitis is caused by pyogenic infections, rheumatic fever, syphilis and tuberculosis Unusual causes of chronic mediastinitis are actinomycosis or streptotricosis, pneumoconiosis and chronic paragonimiasis. The following general statements can be made in regard to chronic mediastinitis. (1) The chronic lesions produce fibrosis, which may constrict the innominate veins or the superior vena cava Edema of the face, neck and upper extremities and the appearance of collateral circulation ensues. (2) If the infection extends to and involves the pericardium, there are edema of the feet and legs, ascites, dyspnea, cyanosis and cough (3) If collateral circulation is established, there are enlarged superficial veins over the thorax and abdomen As the scarring tightens, stenosis of the trachea or bronchi ensues which may be evident symptomatically and on roentgenologic examination Paralysis of the recurrent laryngeal nerves is manifested by changes or loss of voice

The roentgenologic examination confirms the symptoms and the physical findings by revealing a dense shadow which protrudes laterally, slightly beyond the costosternal borders Such a roentgenologic finding is diagnostic unless accompanied by a history and the presence of a known disease which could cause a mediastinal fibrosis or tumor.

Chronic Mediastinal Abscess. ***Chronic Abscess of the Anterior Mediastinum.*** Chronic abscesses in the anterior mediastinum may be caused by tuberculosis, syphilis, actinomycosis and infected mediastinal dermoid cyst If there should be symptoms, they result from the primary disease, for these abscesses are usually without manifestations of their own

Percussion directly over the abscess yields dullness and often tenderness This is the only finding on physical examination suggestive of abscess in the anterior mediastinum The findings on percussion, when taken in conjunction with the history and the results of roentgenologic examination, may be diagnostically conclusive

Chronic Abscess of the Posterior Mediastinum. An abscess of the posterior mediastinum may be caused by perforation of the esophagus, or by extension of infection from osteomyelitis of a vertebra, or from infection in the retropharynx, the lung, pleura or abdominal cavity. Occasionally an abscess may arise in situ from diseased mediastinal lymph nodes

The first symptoms are those of pressure. There are pain, dysphagia, cough and dyspnea The pain is increased by swallowing or coughing It is situated between the scapulae and often extends around toward the front of the thorax The abscess may rupture into a bronchus with expectoration of pus Esophageal rupture creates a serious condition

On physical examination there may be dullness over the spinal column with

increase in voice sounds Abscesses in the posterior mediastinum sometimes rupture into the trachea or bronchi, the esophagus or pleural cavity. Occasionally they appear in a posterior triangle of the neck. Those which extend into the retroperitoneal space may manifest themselves in the groin

Abscesses in the posterior mediastinum may disappear soon after drainage is established through rupture into the esophagus, the trachea or a bronchus.

The diagnosis is seldom made until rupture occurs. However, if the condition is suspected, the ingestion of barium sulfate by the patient enables visualization of the esophagus displaced ventrally Often there is evidence of obstruction due to pressure. Abscesses in other mediastinal parts, if they should occur, are not diagnosable

MEDIASTINAL EMPHYSEMA

Air in the mediastinum may follow severe coughing, crying, lifting, straining at stool, thoracic injuries, overdistention of the lungs, surgical procedures on the lungs and pleura, the use of positive-pressure anesthesia, spontaneous interstitial pulmonary emphysema, pulmonary diseases such as bronchopneumonia, influenza, asthma and tuberculosis, and a ruptured abdominal viscus.

On reaching the mediastinum, air travels along courses of least resistance toward the cervical, occasionally toward the abdominal regions In the neck air localizes in the subcutaneous tissues where it is detected by means of the crepitations elicited on palpation. The air reaching the retroperitoneal space may rupture through the peritoneum and result in pneumoperitoneum, or it may course downward through [illegible] eous emphysema of the thighs and abdominal [illegible] en there is no rupture of an abdominal viscus,

SYMPTOMS Often the escape of air into the retroperitoneal space and into the region of the neck is accomplished with but mild discomfort However, if air reaches the mediastinum under high pressure, as for instance from a high pressure pneumothorax, the pain is excruciating The pain may extend to the left shoulder and the left arm There is a sense of pressure beneath the sternum. Swallowing and turning the head are painful. There are severe dyspnea and cyanosis When the intramediastinal pressure approaches zero, the return flow of blood to the auricles is lessened through compression of the systemic and pulmonary veins

EXAMINATION There is often swelling of the cervical region when the subcutaneous emphysema is marked The presence of swelling over the abdomen, the inguinal region, and the thighs may signify subcutaneous emphysema in these regions

A subcutaneous emphysema is characterized by crepitations on palpation of the subcutaneous tissue When considerable air has accumulated in the mediastinum, the percussion note over the sternum becomes hyperresonant On auscultation, crackling, popping sounds are heard over the sternum and over the surface of the neck and along its borders which are increased when the heart is in systole

DIAGNOSIS The physical findings are diagnostic In instances in which diagnostic uncertainties prevail, lateral roentgenograms may be very helpful.

Usually the prognosis is excellent In most cases of mediastinal emphysema treatment is not required

In instances of acute mediastinal emphysema the syndrome of acute coronary occlusion may be simulated A short period of observation plus electrocardiographic studies will identify the condition present

TUMORS OF THE MEDIASTINUM

Infections may reach the mediastinal lymph nodes from the neck, the abdomen, the lungs and pleura and the surface of the thorax and cause them to enlarge. The tubercle bacillus is the chief cause of the enlargement, but other agents also, such

as infectious mononucleosis, syphilis, Hodgkin's disease, sarcoma, sarcoidosis and carcinoma, cause enlargement of these nodes.

In children a lobe of the thymus protrudes laterally so as to cast a roentgenologic shadow which may resemble that present in disease of the upper pulmonary lobe. Tumors of the thymus or persistent thymus may be revealed by roentgenoscopic examination

Likewise the thyroid gland may extend substernally into the thorax and result in pressure on the trachea, esophagus, internal jugular vein, carotid artery and the recurrent laryngeal and cervical sympathetic nerves.

Cysts of the mediastinum may be congenital, inflammatory or parasitic in origin. The common tumors of the mediastinum are congenital, namely, dermoid or teratoma, cystic lymphangioma, pericardial celomic cyst, bronchial cyst, gastric cyst, and enteric cyst.

Benign tumors as well as malignant growths often result in pressure symptoms.

SYMPTOMS. Tumors of the mediastinal structures are manifested by symptoms referable to the circulatory system, the respiratory system, the mediastinal nerves, and the digestive system These symptoms are very much the same whether produced by a benign or a malignant growth since they originate largely from pressure of the enlarging tumor

Circulatory Symptoms. When obstruction of the superior vena cava is present, the patient, on arising after stooping or flexing the body, for a minute or two has cyanosis of the face, neck and upper part of the thorax. The superficial veins of these regions become more dilated and engorged than those of a normal person who performs a similar act The engorgement of the face in cases of mediastinal pressure will remain for some time, in contrast to the rapidity with which this flushing will disappear in the normal person In instances of marked obstruction the face may be a bluish black, markedly bloated, and the eyes may bulge as is seen in strangulation Venous obstruction may produce cerebral congestion resulting in dizziness, tinnitus, headache and even loss of consciousness Instances of unilateral venous obstruction often can be demonstrated by having the patient raise both arms to a horizontal position above the level of the upper limits of the heart chambers If unilateral obstruction should be present, the superficial veins of one arm will become distended and remain so while the arm is maintained in the horizontal position

Respiratory Symptoms. A patient who has mediastinal pressure producing respiratory symptoms has dyspnea and cough. The dyspnea at first appears on exertion As the pressure increases, it is paroxysmal or continuous

In the beginning the cough is dry Later, when sputum appears, it is mucoid and finally it becomes mucopurulent, and hemoptysis is common The cough and expectoration result from pressure and obstruction of the air passages, and thus from an obstructive bronchitis.

Respiratory symptoms may be due to traction or pressure on the trachea or large bronchi, or to circulatory obstruction Respiratory stridor and wheezing result from pressure causing narrowing of the trachea or bronchi. Occasionally these symptoms are associated with involvement of the recurrent laryngeal nerve.

Gastrointestinal Symptoms. Vomiting, dysphagia and a sense of strangulation are induced by direct esophageal pressure or irritation of the recurrent laryngeal nerve.

Symptoms of Involvement of Mediastinal Nerves A patient who has a mediastinal tumor which is irritating the recurrent laryngeal nerves has hoarseness or complete aphonia There may be the brassy type of cough formerly considered characteristic of an aneurysm of the aorta

As the result of pressure on the sympathetic nerves, constriction of the pupil on the affected side is frequently an early manifestation. Pressure on a sympathetic nerve may be manifested by unilateral sweating and flushing of the face Vagus

pressure resulting in a slow pulse and hiccough from phrenic nerve involvement is rare but does occur.

A dull aching pain is usually an early symptom Paroxysms of intense pain or a prolonged period of excruciating type of pain may be witnessed. There is a sense of oppression or substernal tightness Pressure on the intercostal nerves may result in neuralgia or neuritis and herpes zoster Pleuritic pain is frequent. Erosion of the vertebrae or the sternum produces the boring pain which occurs so often at night in all bone diseases

EXAMINATION On examination there may be observed exophthalmos, and dilatation, contraction or inequality of the pupils. Edema, cyanosis or unilateral flushing and perspiration of the face may be apparent. There is dyspnea on exertion early in the disease If dyspnea should be well established on slight exertion or while at rest, orthopnea is present

A slight fullness of the intercostal spaces near the sternum or a bulging of the sternum in the midline is usually present in dyspneic patients. A nonexpansile pulsation of the bulging region is likewise often observed. The tumor may be visible in the sternal notch or above the sternoclavicular articulation If the mediastinal involvement results from a tumor which arose in the neck, this fact is obvious

. Evidences of interference with the circulatory organs are manifested late in the disease There is usually unilateral dilatation of the veins of the thorax, neck and occasionally the face. The jugular veins are prominent and the veins between the clavicle and the third or the fourth rib anteriorly are distended and tortuous. Occasionally the distended and tortuous veins can be seen on the back below the diaphragm Local cyanosis and edema corresponding in area with the venous dilatation are constantly present

The neck, the sternal notch and the axilla are palpated to determine the presence of tumors or enlarged lymph nodes Enlarged nodes may be felt in the axilla, in the supraclavicular region, or along the lower border of the pectoral muscle. Palpation may reveal deviation and fixation of the larynx and trachea A tracheal tug is more frequently associated with an aortic aneurysm but it may be present in other mediastinal tumors There is often a decreased expansion of the thorax The pulse may be slow from vagal irritation or fast from a weak heart Inequality of the two radial pulses from unilateral interference with the arterial circulation is often present.

Submanubrial dullness may be elicited on percussion This dullness rarely can be demonstrated, however, unless it extends beyond the sternal edge. The area of dullness is often irregular in outline and extensive In some posterior tumors, percussion over the thoracic spines may demonstrate an abnormal flatness to percussion, unless the tumor is large, however, there will be no definite dullness on percussion. In large tumors there is decreased or absent vocal fremitus over the area of percussion dullness

On auscultation, in some instances of large tumors, there is an increased transmission of tracheal respiration in the dull area over the manubrium and absent or diminished transmission of voice or breath sounds over other areas. If there should be pressure on a main bronchus, respiratory sounds on one whole side of the thorax may be suppressed or absent Medium, coarse, piping or musical rales may be heard in one or both lungs as a result of pressure of bronchitis

DIAGNOSIS. The presence of manifestations of mediastinal pressure which affects the mediastinal circulation, respiration, or nerves singly or in combination is clinically unmistakable The nature of the tumor, as to whether it is benign, malignant or of vascular origin (aneurysm), can often be determined by the roentgenologist.

Teratomas and dermoid cysts occur behind the sternum, rarely in the posterior mediastinum, in patients less than 30 years of age. Difficulty in diagnosis of these follows perforation into a bronchus with the ensuing infection.

as infectious mononucleosis, syphilis, Hodgkin's disease, sarcoma, sarcoidosis and carcinoma, cause enlargement of these nodes.

In children a lobe of the thymus protrudes laterally so as to cast a roentgenologic shadow which may resemble that present in disease of the upper pulmonary lobe. Tumors of the thymus or persistent thymus may be revealed by roentgenoscopic examination

Likewise the thyroid gland may extend substernally into the thorax and result in pressure on the trachea, esophagus, internal jugular vein, carotid artery and the recurrent laryngeal and cervical sympathetic nerves.

Cysts of the mediastinum may be congenital, inflammatory or parasitic in origin The common tumors of the mediastinum are congenital, namely, dermoid or teratoma, cystic lymphangioma, pericardial celomic cyst, bronchial cyst, gastric cyst, and enteric cyst.

Benign tumors as well as malignant growths often result in pressure symptoms.

SYMPTOMS. Tumors of the mediastinal structures are manifested by symptoms referable to the circulatory system, the respiratory system, the mediastinal nerves, and the digestive system. These symptoms are very much the same whether produced by a benign or a malignant growth since they originate largely from pressure of the enlarging tumor

Circulatory Symptoms. When obstruction of the superior vena cava is present, the patient, on arising after stooping or flexing the body, for a minute or two has cyanosis of the face, neck and upper part of the thorax. The superficial veins of these regions become more dilated and engorged than those of a normal person who performs a similar act The engorgement of the face in cases of mediastinal pressure will remain for some time, in contrast to the rapidity with which this flushing will disappear in the normal person In instances of marked obstruction the face may be a bluish black, markedly bloated, and the eyes may bulge as is seen in strangulation Venous obstruction may produce cerebral congestion resulting in dizziness, tinnitus, headache and even loss of consciousness. Instances of unilateral venous obstruction often can be demonstrated by having the patient raise both arms to a horizontal position above the level of the upper limits of the heart chambers. If unilateral obstruction should be present, the superficial veins of one arm will become distended and remain so while the arm is maintained in the horizontal position

Respiratory Symptoms. A patient who has mediastinal pressure producing respiratory symptoms has dyspnea and cough. The dyspnea at first appears on exertion As the pressure increases, it is paroxysmal or continuous

In the beginning the cough is dry Later, when sputum appears, it is mucoid and finally it becomes mucopurulent, and hemoptysis is common. The cough and expectoration result from pressure and obstruction of the air passages, and thus from an obstructive bronchitis.

Respiratory symptoms may be due to traction or pressure on the trachea or large bronchi, or to circulatory obstruction. Respiratory stridor and wheezing result from pressure causing narrowing of the trachea or bronchi Occasionally these symptoms are associated with involvement of the recurrent laryngeal nerve

Gastrointestinal Symptoms Vomiting, dysphagia and a sense of strangulation are induced by direct esophageal pressure or irritation of the recurrent laryngeal nerve.

Symptoms of Involvement of Mediastinal Nerves A patient who has a mediastinal tumor which is irritating the recurrent laryngeal nerves has hoarseness or complete aphonia. There may be the brassy type of cough formerly considered characteristic of an aneurysm of the aorta.

As the result of pressure on the sympathetic nerves, constriction of the pupil n the affected side is frequently an early manifestation. Pressure on a sympathetic erve may be manifested by unilateral sweating and flushing of the face Vagus

Inspection does not reveal abnormalities On first palpation and percussion there are no abnormal signs By the time the sputum begins to be profuse and to collect in the bronchial tubes, vibrations produced by it on breathing may be felt on the surface of the thoracic wall. On auscultation there are sibilant sonorous bronchial rales Later, coarse, moist and bubbling rales are heard. Coughing may result in a temporary disappearance of rales. The breath sounds may be masked by the numerous rales throughout the thorax The physical signs in acute bronchitis are usually elicited equally well over both sides of the thorax When the physical signs are encountered over only a part of one lung, the condition therein is a more serious condition than acute bronchitis

Diagnosis is established by physical examination Acute bronchitis may be a serious disease in infants and elderly persons, especially in those who have emphysema, asthma or heart disease In otherwise normal persons recovery is the rule Occasionally an acute bronchitis progresses and pneumonia develops

Acute Bronchiolitis (Capillary Bronchitis). An acute inflammation, mainly of the walls of the bronchioles, is caused by bacteria and probably viruses The first symptoms are often those of an acute respiratory infection The symptoms become more severe and soon dyspnea and then cyanosis develop The temperature rises to 103 or 104 F (39 4 or 40 C). The cough is distressing Moderate prostration ensues.

The patient appears to be seriously ill There are cyanosis, profuse perspiration, shallow and rapid breathing Findings on palpation and percussion are normal throughout the lungs Auscultation reveals early in the course of the disease sibilant rales and, later, fine, moist rales throughout the lungs

Cultures of the sputum reveal a preponderance either of the influenza bacillus or of the hemolytic streptococcus [illegible]

The results of roentgenologic examination likewise are indefinite This condition simulates a diffuse bronchial pneumonia If the course is favorable, the diagnosis may not be made, otherwise the diagnosis awaits necropsy

Oxygen, chemotherapy or antibiotics are desirable

Chronic Bronchitis. Chronic bronchitis in adults occurs in those debilitated by tuberculosis, emphysema, circulatory insufficiency, bronchiectasis, allergic conditions, infection of the paranasal sinuses, pneumoconiosis, fungous infections, fusospirochetal infections, foreign bodies, dust and benign or malignant tumors The aged are prone to have this disease

The cough is constantly present and tiresome Soon after meals the cough may cause vomiting and thus adds to the weakness and often loss of weight The cough and expectoration are always worse on breathing of cold damp air The muscles of the lower thoracic wall, and particularly those of the upper abdominal wall, may become sore and tender to a degree that an intra-abdominal disease may be suspected

The eyes are often reddened and the lids may be hemorrhagic from the cough. An emphysematous-shaped chest is present. The lungs are hyperresonant on percussion and there are musical rales on auscultation These may clear on deep breathing Medium and fine rales may be elicited over the bases which do not clear on deep breathing The breath sounds may be somewhat diminished and the expiratory phase of respiration is longer and lower pitched than usual On palpation of the upper part of the abdomen there may be diffuse soreness and tenderness of the muscles Palpation and percussion often reveal evidence of primary disease of the circulatory apparatus

The diagnosis is established by a process of elimination of primary disease such as tuberculosis, heart disease, malignant disease, fungous infections and pressure on the trachea or bronchi

Malignant tumors of the thymus may be suspected if there should be the accompanying symptoms of myasthenia gravis. Lymphosarcoma (Hodgkin's type) is usually manifested by involvement of the lymph nodes of the neck before there is manifest mediastinal pressure.

Aneurysms can usually be determined by roentgenoscopic examination.

Invasion of the mediastinum by malignant neoplasms from elsewhere in the body occurs by direct extension or by lymphogenous or hematogenous spread Direct extension to the mediastinum occurs in carcinoma of the trachea, bronchi, esophagus and breast. Carcinoma of the breast may also metastasize by the blood stream or the lymph stream. Lymphatic and blood-stream metastasis to the mediastinum is extremely rare The symptoms and physical findings are evidence of pressure on one or more of the mediastinal contents Diagnosis usually depends on recognition of the primary tumor

Except for secondary invasion of mediastinal structures by sarcomatous growths, sarcoma is rare. Metastatic involvement of the mediastinum from axillary melanosarcoma and bone sarcoma has been reported. Besides the signs and symptoms of the primary growth, those of pressure or invasion of mediastinal structures may be found.

DISEASES OF THE BRONCHI

The Bronchial System. The *right main bronchus* is larger than the left and is more nearly a continuation of the trachea The right main bronchus divides into the right upper, the middle, the dorsal and lower branches

The *right upper lobe bronchus* divides into three segmental branches (1) right anterolateral segment, (2) right posterolateral segment, and (3) right apical segment.

The *right middle lobe bronchus* divides into two major branches, one of which supplies the right anterior middle segment and the other supplies the right lateral middle segment of the lung

The *dorsal bronchus* divides into the anterior, posterior and middle bronchi which supply lower lobes of the lung

The *lower branch* divides twice into the mid, posterior and anterior basic branches

The *left main bronchus* is immediately more branching in character than the right main bronchus The first division of the left main bronchus divides into the left upper lobe bronchus, the anterolateral, the lateral mid, anterior mid, anterior basic, mid basic, posterior basic and dorsal bronchi

The Bronchi and Lungs as Originators of Pain. Clinically, according to Jackson, pain is almost never noted during bronchoscopic manipulations, even in dealing with sharp-pointed foreign objects which inevitably inflict some trauma Occasionally a patient with a bronchial foreign body is able to localize it correctly as to side. Real pain is extremely rare in these cases unless there is pleural involvement Pain does appear to be felt more in the bronchi than in the trachea, but possibly this is due to the proximity to the pleura

Acute Bronchitis. Acute bronchitis is usually a part of a catarrhal inflammation of the bronchi, trachea and larynx It frequently begins as an acute infection of the respiratory tract.

... by mechanical
... ire

... sa-
tion in the throat and beneath the sternum may be distressing From 1 to 2 days after the onset the sputum may become profuse *Quantities of yellowish* greenish stringy mucous material, sometimes with a fetid odor and often blood streaked, may be expectorated. In some instances the onset may be with fever (temperature 100 to 101 F, or 37.8 to 38 3 C). There is generalized aching, particularly severe over the lumbar region and down the legs Except in those who have asthma and chronic conditions of the bronchial tree, the symptoms pass in 3 to 5 days

The age and sex of the patients fail to show marked differences in the types of the disease. Blood-spitting is commoner with saccular dilatation than with other types. In Chapman and Wiggins' series of cases blood-spitting had occurred in 42 per cent for more than 2 years About one half estimated the amount at 1 ounce (30 ml) or less in 24 hours About 40 per cent were unaware of having had pneumonia. The incidence of pneumonia in saccular bronchiectasis was greater than in the cylindric type. Influenza if present was unknown to 27 per cent. There was no significant difference in its incidence among the three types. Nasal disease was a complaint of 35 per cent Its incidence was about the same in the three types. Physical signs were absent more often in cylindric bronchiectasis than in the other types The only patients known to have asthma were in the cylindric group. These data on the distribution of the disease differ in that there was a relatively higher incidence in the right lower lobe as compared with the left. This is unexpected in view of the fact that congenital bronchiectasis should involve the left lower lobe more commonly It appears that distinction between cylindric and saccular bronchiectasis is based on sound statistical grounds This is not the case with other morphologic types

In advanced disease extensive fibrosis, emphysema and cavities are present. Occasionally an abscess may appear in a part of the lung not involved by bronchiectasis as the result of aspiration of infected material from the involved bronchi.

In the so-called dry type of bronchiectasis the parenchymal changes are slight, but in some patients the fibrosis continues to develop until it extends throughout the lung or lungs As the fibrosis progresses, compensatory emphysema obscures the physical signs of the disease

There are both congenital and acquired forms of bronchiectasis Regarding the congenital form of bronchiectasis, Olsen stated that the condition in the lungs is manifested in almost half of the cases before the age of 10 years and that it follows an attack of influenza, measles, pertussis or pneumonia. Often there is an associated dextrocardia

Acquired bronchiectasis develops after streptococcal bronchopneumonia either in childhood or in adulthood First the changes involve the bronchial mucosa, the submucosa and the pulmonary parenchyma Progression of these changes results from recurring bronchopneumonia The chronic stasis and infection distal to a bronchial stenosis or obstruction from any cause sequentially induce development of bronchopneumonia, pulmonary abscess and, later, indurative pneumonia and bronchiectasis

Symptoms Small regions of bronchiectasis are often symptomless, but such small regions may be the point of origin of severe hemorrhages In those who have symptoms, paroxysms of coughing when the patient changes position, often soon after getting out of bed in the morning, are common The cough may or may not bring up large quantities of sputum The paroxysms of cough may last from a few minutes to an hour or more

Pulmonary hemorrhage is a common complaint of those who have bronchiectasis Vinson found that in 100 cases of chronic bronchiectasis there were histories of pulmonary hemorrhage in 49 According to Vinson these pulmonary hemorrhages are not predictable on the basis of degrees of involvement of the lung tissues, or of prodromal symptoms

In many instances the patient often has observed that on bending forward while coughing a large amount of sputum is obtained

Examination Inspection reveals widening of the intercostal spaces, retraction and lagging of the thoracic wall, and perhaps the absence of the phrenic wave signs (Litten's sign). Clubbing of the fingers and the toes often appears soon after the onset of the symptoms The clubbing may involve only the soft tissues or may be associated with hypertrophic pulmonary osteoarthropathy. Dyspnea is present when there are advanced pulmonary fibrosis and emphysema.

On palpation tactile fremitus may be increased or normal, depending on the amount of pulmonary fibrosis and its proximity to the periphery of the lungs.

Fibrinous Bronchitis. This form of chronic bronchitis is called also pseudomembranous, membranous croupous, mucinous, and plastic bronchitis.

The etiology of fibrinous bronchitis is not known. The condition, in addition to other symptoms of bronchitis, is characterized by the *expectoration of casts of* fibrinous mucous material The casts have the shape of the bronchial ramification in which they were formed.

In the acute stage of the disease cough, chills and fever are present which are *followed by pain and dyspnea and expectoration of the casts. In the chronic stage* the symptoms are mild but prolonged. Hemoptysis is common after expectoration of the casts.

On examination the findings are those of chronic bronchitis In diagnosis the presence of the casts in the sputum is the only distinguishing feature of this form of chronic bronchitis from all others

Tracheobronchial Tuberculosis. Tracheobronchial tuberculosis is frequent in primary pulmonary tuberculosis of children and adolescents and in the re-infection type of pulmonary tuberculosis in adults

The bronchial mucosa is frequently the seat of both tuberculous and non-tuberculous lesions. The bronchi are either compressed by the enlarged lymph nodes or retracted by sclerosis of the pulmonary lesions. The evolution of tuberculous bronchial lesions runs parallel with the evolution of the tuberculous process in the involved lobe. Acute exudative bronchial tuberculosis appears in some cases years after the regression of the pulmonary tuberculosis and its calcification

The symptoms are often those of an asthmatic or chronic bronchitis. The diagnosis is established by demonstration of tubercle bacilli, and by bronchoscopic and roentgenologic examination followed by histologic and cultural examinations of biopsy tissue

Broncholithiasis (Pneumoliths or Lung Stones). Broncholiths are composed largely of calcium Lung stones may be present in inspissated pus, in regions of tuberculous caseation in lymph nodes and lungs, around aspirated foreign bodies

Broncholiths may develop within the bronchi or may originate outside the *bronchi, with subsequent perforation into the air passages. In the* majority of cases broncholiths are due to perforation of calcified tuberculous lymph nodes into the bronchus The changes found in the presence of broncholiths may simulate carcinoma of the lung, chronic pulmonary abscess, bronchiectasis with atelectasis and *chronic pneumonitis as well as mycotic disease Body section* roentgenography is of diagnostic aid in bronchopulmonary lithiasis

The clinical symptoms may vary from complete absence of signs or symptoms to those of a severe or critical illness Practically every pathologic condition which *may develop in the thorax may be simulated. Bronchopulmonary* lithiasis should be included in differential diagnosis of bronchial obstruction, pulmonary suppura-

of the bronchial wall through which the stone has passed. The diagnosis is not frequently made. The patient expectorates a stone, followed by a small amount of blood and the illness is over without the physician knowing anything about it

[illegible] of the

ural

part

of one lobe of either lung, in the base, or the disease may affect bronchi [illegible] iout the greater part of both lungs.

The types of bronchial dilatations by roentgenographic study are the cylindric, saccular, varicose, fusiform and bronchiolectatic; with the cylindric, saccular and varicose forms being the common types.

The age and sex of the patients fail to show marked differences in the types of the disease. Blood-spitting is commoner with saccular dilatation than with other types In Chapman and Wiggins' series of cases blood-spitting had occurred in 42 per cent for more than 2 years. About one half estimated the amount at 1 ounce (30 ml) or less in 24 hours About 40 per cent were unaware of having had pneumonia The incidence of pneumonia in saccular bronchiectasis was greater than in the cylindric type. Influenza if present was unknown to 27 per cent. There was no significant difference in its incidence among the three types. Nasal disease was a complaint of 35 per cent Its incidence was about the same in the three types. Physical signs were absent more often in cylindric bronchiectasis than in the other types. The only patients known to have asthma were in the cylindric group These data on the distribution of the disease differ in that there was a relatively higher incidence in the right lower lobe as compared with the left This is unexpected in view of the fact that congenital bronchiectasis should involve the left lower lobe more commonly It appears that distinction between cylindric and saccular bronchiectasis is based on sound statistical grounds This is not the case with other morphologic types

In advanced disease extensive fibrosis, emphysema and cavities are present. Occasionally an abscess may appear in a part of the lung not involved by bronchiectasis as the result of aspiration of infected material from the involved bronchi.

In the so-called dry type of bronchiectasis the parenchymal changes are slight, but in some patients the fibrosis continues to develop until it extends throughout the lung or lungs As the fibrosis progresses, compensatory emphysema obscures the physical signs of the disease.

There are both congenital and acquired forms of bronchiectasis Regarding the congenital form of bronchiectasis, Olsen stated that the condition in the lungs is manifested in almost half of the cases before the age of 10 years and that it follows an attack of influenza, measles, pertussis or pneumonia. Often there is an associated dextrocardia.

Acquired bronchiectasis develops after streptococcal bronchopneumonia either in childhood or in adulthood First the changes involve the bronchial mucosa, the submucosa and the pulmonary parenchyma Progression of these changes results from recurring bronchopneumonia The chronic stasis and infection distal to a bronchial stenosis or obstruction from any cause sequentially induce development of bronchopneumonia, pulmonary abscess and, later, indurative pneumonia and bronchiectasis

SYMPTOMS Small regions of bronchiectasis are often symptomless, but such small regions may be the point of origin of severe hemorrhages. In those who have symptoms, paroxysms of coughing when the patient changes position, often soon after getting out of bed in the morning, are common The cough may or may not bring up large quantities of sputum The paroxysms of cough may last from a few minutes to an hour or more

Pulmonary hemorrhage is a common complaint of those who have bronchiectasis Vinson found that in 100 cases of chronic bronchiectasis there were histories of pulmonary hemorrhage in 49 According to Vinson these pulmonary hemorrhages are not predictable on the basis of degrees of involvement of the lung tissues, or of prodromal symptoms

In many instances the patient often has observed that on bending forward while coughing a large amount of sputum is obtained

EXAMINATION Inspection reveals widening of the intercostal spaces, retraction and lagging of the thoracic wall, and perhaps the absence of the phrenic wave signs (Litten's sign) Clubbing of the fingers and the toes often appears soon after the onset of the symptoms The clubbing may involve only the soft tissues or may be [illegible] when

[illegible] depending on the amount of pulmonary fibrosis and its proximity to the periphery of the lungs

Fremitus is decreased if the pleura is thickened. In the presence of emphysema of the lungs, there is a decrease in tactile fremitus

On percussion, changes are present in those who have a thickened pleura and emphysematous regions

The auscultatory findings are often within normal limits. Occasionally there are fine to coarse and intermittent rales, depending on whether or not the contents of the sacculations of the bronchi have been expectorated The breath sounds may be bronchial or cavernous when there are large empty bronchiectatic cavities.

On endoscopic examination there may be discovered a foreign body or some other obstruction, the removal of which, if feasible, facilitates treatment or cures the patient.

With the head and shoulders nearly to the floor, forced coughing will often be followed by the expectoration of a large amount of sputum Within a 24 hour period a volume of sputum equaling 2 pints (1 liter) or more may be expectorated. The sputum is often blood streaked and in it are greenish yellow masses ½ inch to 1 inch (1.27 to 2.5 cm) in diameter (Traube's or Dittrich's plugs). When allowed to stand, the sputum separates into three layers The bottom layer is opaque with pus, cellular debris, bacteria and occasionally elastic fibers, the middle layer appears somewhat clear and watery, and the top layer is frothy. The sputum is examined for tubercle bacilli since tuberculosis may coexist with or be the cause of bronchiectasis

Diagnosis The diagnosis is suspected from the history and is confirmed on the examination Usually the pulmonary involvement is detected on roentgenologic examination An endoscopic examination is often invaluable in detection of a localized bronchial stenosis or of a foreign body obstructing a bronchus

Postural drainage should be instituted at once The surgical removal of the involved lobe, or even the entire lung when necessary, is satisfactory if the patient survives the operation and the patient is not left with an incapacitating postoperative thoracic pain

Bronchostenosis. Bronchostenosis may develop from pressure extrinsic to a bronchus or from inflammation or growths from within its walls Conditions which cause bronchostenosis also cause bronchial occlusion. Prickman and Moersch examined endoscopically 140 patients suffering from asthma, in 60 of whom definite stenosis was found in one or more bronchi

A significant and prominent symptom is severe, persistent and sometimes paroxysmal cough, often of long duration and dating from an acute respiratory infection At times it may be impossible for the patient to cough up the sputum Then at times the cough loosens and there is profuse, mucopurulent sputum streaked with blood This increased amount of sputum represents some of the secretions which have been retained by the stenosis Bronchostenosis may result in pneumonitis and atelectasis and if not relieved, bronchiectasis may ensue

The physical signs are those of pneumonitis and atelectasis Often a wheeze is elicited, and occasionally crepitant rales are heard.

A presumptive diagnosis of bronchostenosis is often made from the history and physical findings The exact diagnosis is made only by the bronchoscopist or the roentgenologist

Bronchial Perforation. Acute or chronic pyogenic abscesses, chronically inflamed lymph nodes containing lung stones, and lesions of chronic pulmonary tuberculosis may perforate ramifications of bronchi and discharge their contents into the bronchial system. Materials thus discharged are distributed peripherally, and in the case of tuberculous material acute pulmonary tuberculosis may ensue

The symptoms are those of the prevailing disease.

Results of examination often are negative In some instances tubercle bacilli may be found in the sputum or gastric washings although the lungs appear entirely clear on examination

The diagnosis is made by a capable bronchoscopist

Bronchial Fistulas. Bronchial fistulas are often the sequence of perforations of the viscera of the abdominal cavity After perforation of abdominal viscera a subphrenic abscess forms with subsequent perforation of the diaphragm and into a bronchus. In the course of empyema or subphrenic abscess bronchocolic fistula may develop.

The symptoms are obscured by those of subphrenic abscess

The diagnosis is often difficult; however, Escherichia coli found in abundance in the sputum or an abundance of pus in the feces is suggestive. Bronchography may suffice if the iodized oil enters the fistulous tract and empties into the colon. If this method fails, a barium enema may be helpful if the barium enters the bronchial system When the fistula fails to close, surgical treatment may be indicated.

Bronchobiliary Fistulas. Bronchobiliary fistulas develop when hepatic abscesses penetrate the diaphragm and a communication is established with one of the larger bronchi Common causes are amebic and echinococcal infections of the liver The sequence of events in an occasional case is the formation of gallstones followed by suppurative cholangitis with perforation, and formation of a small subphrenic abscess with perforation of the diaphragm and a bronchial ramification.

The diagnosis can be made when the patient expectorates bile. In some cases roentgenologic examination following the administration of iodized oil reveals the fistulous tract When such fistulas do not close, surgical intervention may be considered

Broncho-esophageal fistulas are usually fatal However, an occasional patient is observed who has a fistula which has slowly developed as the result of some chronic disease in the esophagus or in a bronchus who has lived for a long time In rare instances broncho-esophageal fistula has followed pneumonia and the patient may have lived for a long time on very low fluid intake to avoid coughing when liquids were swallowed

The symptoms of a broncho-esophageal fistula are cough and dysphagia immediately after swallowing food or drink unless the liquid is taken in sips Paroxysmal half-vomiting and half-coughing characterize this type of dysphagia

It is important to determine the general physical condition and to discover evidence of the underlying disease There are no physical signs indicative of these fistulas

If one of these fistulas is suspected, endoscopic examination of the esophagus is diagnostic.

Bronchial Obstructions and Pulmonary Atelectasis. Xalabarder defined atelectasis as the absence of air in the pulmonary alveoli with intense retraction and shrinking, the latter differentiating it from simple pulmonary collapse. As a result of the vascular dilatation characteristic of atelectasis intra-alveolar exudates from simple serous edema to hemorrhagic suffusions are produced Reversion is likely to occur, but if inflammation persists a long time a progressive fibrosis prevails The mechanisms of the production of atelectasis are not always obvious, for (1) there are bronchial obstructions without atelectasis, (2) the existence of bronchial plugs is not constant, (3) atelectasis can be produced by obstruction of a main bronchus but not of a secondary bronchus, and (4) once the gaseous pressure on each side of the alveolar wall has become equal, the alveolus will be relaxed to the maximal limit which its elastic structure permits

Xalabarder has expressed the belief that atelectasis is produced by pulmonary contraction and that it originates from several causes acting on a specially predisposed organ One of these causes may be bronchial obstruction, but this is not an indispensable factor Atelectasis is the abnormal exaggeration of the physiologic pulmonary tone This defective function is of importance in the genesis of other pulmonary phenomena including the active dilatation of the lung (insatiable pneumothorax and functional emphysema) Xalabarder accepted the existence of muscular fibers in the alveolar walls and saw in the functioning of these muscular plexuses,

under regulation by the autonomic nervous system, the solution to a regional contracture in the affected pulmonary zone, that is to say, to atelectasis.

Congenital Pulmonary Atelectasis. Respiratory movements take place during the second half of intra-uterine life, and thus some of the intrapulmonary spaces are occupied by amniotic fluid This fluid may cause changes in the lungs which prevent full expansion of the lungs at birth. A failure on the part of the lung to expand may also be due to the congenital absence of alveoli, to bronchial atresia or to obstruction of bronchi.

A widespread atelectasis may prevent breathing by the newborn child In the lungs of the newborn there may be regions of atelectasis which are permanent and which do not cause symptoms These regions of the lung are sealed off and leave only a strand of fibrous tissue When regions of the lung thus degenerate fully, symptoms never occur.

In the lungs of some adolescents and adults there is a well-established bronchiectasis which has been present since early childhood without inflammation of the lungs These regions represent the so-called dry bronchiectasis which may be discovered during life or may be found at the time of postmortem examination. The regions are often situated in the lower lobe of the left lung In other instances these regions may become infected and the manifestations of atelectasis ensue

Obstructive or Acquired Pulmonary Atelectasis. Normally the bronchi are filled with air and the right amount of secretion. The secretion from the bronchi is drained upward This upward drainage is afforded by the pumping effect of respiration, aided by the upward transportation of small particulate matter by the ciliary activity of the cells lining the bronchi, and finally by the expulsive force of a cough

When a mechanical obstruction develops, its effects depend on its degree, on whether the obstruction is complete or partial, and if partial, on whether it is fixed or movable

Complete bronchial obstruction is immediately followed by absorption of gases and total retraction of the involved part of the lungs There may still remain functioning pulmonary tissue in the region of the obstruction which is supplied by a bronchus tributary to the obstructed bronchus Inflammation or edema interferes with absorption of gas and retraction For instance, a lobe of the lung that is distal to complete obstruction by a foreign body may show evidence of atelectasis, edema and inflammatory infiltration, but owing to an anastomosing communication between the alveoli of each lobe it remains partially or wholly distended These communications between the lobes of the lung are a protection against atelectasis that follows occlusion of the smaller bronchi

Pulmonary atelectasis occurs when there is compression of pulmonary tissue or an obstruction to a bronchus. In either case the lung is unable to expand on inspiration There are several conditions which reduce the size of the thoracic cavity sufficiently to produce atelectasis, for instance fluid or air in the pleura, removal of ribs, or paralysis of the diaphragm Under these circumstances the lungs are forced to adjust themselves to the new volume by retraction Lesions of the central nervous system that cause paralysis of the muscles of inspiration are followed by atelectasis

An obstruction of a bronchus, with subsequent retraction of the lung after the air has been absorbed from it, is a common cause of segmental atelectasis.

Postoperative Atelectasis (*Postoperative Pneumonia*). During and after surgical operations, because of pain and sedation the respirations become shallow, the cough reflex is suppressed and there is an immobilization of the thorax in a fixed posture As the result of these abnormal conditions, aspiration and stagnation of secretion from the upper part of the respiratory tract ensue and often atelectasis supervenes The condition in the lung may remain atelectatic or may become pneumonic. Thus the postoperative atelectasis is often a postoperative pneumonia

Postoperative pulmonary obstruction and consequent atelectasis or pneumonia are commoner when acute respiratory infection is present at the time of operation, or when the patient has been exposed to any acute respiratory infection just prior to operation

From one to four days after the operation, if the patient is mentally alert, there

is a feeling of tightness or constriction in the lower part of the thorax, manifested as an oppression during breathing. In extensive involvement there are dyspnea, cyanosis, cough and expectoration. In all, however, whether there are complaints or not during the first three or four postoperative days, the temperature rises to 101 F (38.3 C) or higher The pulse rate will be fast (120 or more).

In mild illness, temperature and pulse rate return to normal within a week. The pulse rate returns to normal before the fever subsides

In many patients the illness is prolonged and there is pneumonitis, or pneumonia finally terminating in bronchiectasis or death

On examination, when feasible, there may be relative dullness to percussion, enfeebled breath sounds, and fine rales over the lower lobe or lobes Bronchial breathing is often present On occasion a pleural rub may be heard. There is retraction of the intercostal spaces during inspiration The diaphragm is elevated and the apex beat of the heart may be shifted toward the involved side

The diagnosis depends on the history, postoperative course, physical findings and results of roentgenologic examinations It is inadvisable to examine very ill patients physically and, in some cases, roentgenologically

Infection Atelectasis. During the course of respiratory infections degrees of atelectasis are often present The small atelectatic portions of the pulmonary tissue assume normal volume and function as soon as the infection subsides Larger regions, resulting from obstruction of larger bronchi, become clinically manifested Long after a bad cold has passed, a cough and expectoration persist which may be indicative of an unknown atelectasis

During the course of an acute respiratory infection there is acute thoracic pain which is situated in the base of the lung beneath the scapula around to the axillary line, and dyspnea, which, if severe, is accompanied by cyanosis When these symptoms are present, the occlusion is large and there is a virulent infection Under these conditions fever and sometimes chills develop.

On physical examination there is elevation of the diaphragm and shifting of the *mediastinum Over the atelectatic portions of the lung there are altered or absent* breath sounds, rales and varying degrees of consolidation

The history, the physical findings and the findings on roentgenoscopic examination are diagnostic These patients should have an endoscopic examination

Alveolar and Pulmonary Adenomatosis. Benign pulmonary adenomatosis is a disease with multiple involvement of the lungs by a process in which the alveoli are filled with distended columnar cells The similarity between this adenomatous process and the metastasizing alveolar cell tumor is sufficiently close to suggest that pulmonary adenomatosis is a potentially malignant tumor. However, extrapulmonary metastasis is unknown in adenomatosis

Pulmonary adenomatosis may have a possible relation to jagziekte, an epizootic pulmonary adenomatosis of sheep, which is considered to be a viral infection. Like pulmonary adenomatosis, metastasis does not occur in jagziekte The attempts to transmit the condition to animals from material obtained from human beings with pulmonary adenomatosis have failed

The sex incidence is two women to one man. The age of the patients has ranged from 30 to 80 years

The symptoms commence with cough which varies from nonproductive and mild to produc[illegible]
dyspnea, [illegible]
followed [illegible]
process, dyspnea can appear very early and be out of proportion to cough and expectoration

Sputum is profuse, frothy, tenacious, and there is difficulty in expectorating it, despite the fact that there is constant welling up of the material into the throat The

absence of hemoptysis and the presence of frothy tenacious sputum appear to be characteristic features of this disease.

Despite the severe coughing and the expectoration of large quantities of sputum, and the severe dyspnea, a good general physical condition may be maintained for several months.

The findings on physical examination depend on the stage of the disease when the examination is made The findings vary from those of a bronchitis through bronchial pneumonia to lobar pneumonia

The diagnosis is based on severe dyspnea and abundant frothy mucoid sputum without blood streaking in a patient who maintains good general condition for several months and then declines Death due to asphyxiation ensues. Roentgenologic examination and microscopic examinations of the sputum are of no specific diagnostic aid To those who are familiar with the appearance of the sputum, which maintains its frothy nature for hours, the diagnosis is tentatively established by this peculiarity Endoscopic examination is rarely helpful diagnostically

MALIGNANT TUMORS OF THE BRONCHI AND LUNGS

Primary Malignant Lesions. *Bronchogenic Carcinoma.* It is thought that there has been a great increase in the number of authentic bronchogenic carcinomas observed in recent years. Eight of every 10 patients who have bronchogenic carcinoma are men With the ladies smoking, many of them excessively, it seems likely that the high incidence of pulmonary cancer in men is not to be accounted for entirely on a possible carcinogenic role of tobacco and cigarette-paper smoke.

Seven or more of every 10 of these neoplasms arise near the tracheal *bifurcation.* The rest arise from the smaller bronchioles and are designated peripheral pulmonary cancers. The peripheral pulmonary cancers vary from small outgrowths of the bronchial mucous membrane to large soft tumors resembling tuberculosis, including cavity formation

Bronchogenic carcinomas arise from the tunica propria or basement membrane On the basis of cellular classification pulmonary carcinomas may give rise to three types of tumors. (1) stratified squamous, (2) adenocarcinoma, and (3) the undifferentiated, basal cell tumors. The stratified squamous cell tumors are more amenable to surgical removal than are tumors of the other types

Metastasis from these tumors occurs by direct extension and passage through the lymphatic structures and the blood stream, and by bronchial embolism Pulmonary tumors often metastasize to the brain

SYMPTOMS The first symptom may be a dry cough, and if the tumor arises in the large bronchi, there are cough, expectoration and hemoptysis. The cough is unproductive, hacking, irritant and persistent. When expectoration begins, it is at first scanty and mucoid in consistency As the disease progresses, the sputum is copious, foul in odor, mucopurulent and streaked with blood Peripherally situated pulmonary cancers cause pain as an early symptom A sudden or an abrupt onset of cough, pain, dyspnea and hemoptysis or hemorrhage may indicate the occlusion of a bronchus. Hemoptysis varies from blood streaked sputum to a distinct but not a profuse hemorrhage

The pain is variable in intensity It may be sharp, dull, aching or lancinating. Continuous and severe thoracic pain in the absence of pleurisy often occurs in cancer of the lung It is always on the same side of the thorax as the growth, but it may be referred to the neck, shoulder, upper part of the abdomen, back, arms or legs.

In the beginning, dyspnea is only exertional It may be accompanied by wheezing or a paroxysm of asthma which continues as orthopnea

Continuous or intermittent fever is almost always present. Emaciation begins early and advances rapidly as fever increases and the disease progresses Cyanosis is late in the course of the disease. It advances rapidly as death approaches.

EXAMINATION The physical findings in carcinoma of the lung vary with the location, size and rate of growth of the neoplasm. Often there are no abnormalities on examination by physical means until there are coexistent pathologic change and complications secondary to the tumor. The primary malignant disease may thus be obscured.

In well-advanced cancer of the lung the thoracic movement may be limited or absent The limitation of thoracic movement in the beginning is confined to the affected side but later both sides are affected If a sufficient volume of effusion is present, the intercostal spaces bulge. As the pressure increases in the thorax, the veins of the neck and thoracic wall are distended, and edema of the face, neck or arms is present. On palpation enlarged lymph nodes may be felt in the lower triangles of the neck and in the axilla

When the disease is advanced, tactile fremitus is decreased or absent over the diseased side and often is increased on the normal side. The cardiac impulse may be displaced toward the side of the pulmonary lesion

There are no changes in the percussion sounds until a considerable portion of the pulmonary tissue is hardened by the tumor. Then the percussion sound is dull or flat Dullness is often lateral to the sternum with a normal area between the dull space and the clavicle

Auscultation late in the course of the disease may reveal that breath sounds are enfeebled or absent If the neoplasm partially occludes a bronchus, a high-pitched tubular breathing is heard When a tumor closes a bronchus, collapse of the part of the lung supplied by that bronchus takes place As a consequence the breath sounds are absent and both vocal and tactile fremitus are diminished or absent. Like the other physical signs, the rales, in occurrence and nature, are variable.

DIAGNOSIS If possible, the diagnosis is made before signs are present on physical examination The roentgenologic examination is the most important and can be diagnostically accurate in a large percentage of cases of cancer of the lung. The taking of a roentgenogram after iodized oil has been injected into the bronchial tree is helpful in the diagnosis of some bronchogenic cancers

Conclusive proof of the diagnosis depends on biopsy, which may be accomplished by bronchoscopy The absence of bronchoscopic demonstration of cancer of the lung, however, does not preclude the diagnosis of bronchogenic carcinoma, for the bronchoscope cannot reach all parts of the lung In these patients examinations of the sputum for malignant cells may determine the diagnosis

A diagnosis can often be made from a biopsy of lymph nodes of the neck or axilla or other lymph nodes However, when a diagnosis is thus made, surgical treatment is precluded

Artificial pneumothorax, either alone or combined with thoracoscopy, and exploratory thoracotomy are occasionally required for a diagnosis while the lesion is still circumscribed Justification for these procedures requires an evaluation by successful and experienced specialists

Examination of sputum for cancerous tissue or cells has established the fact that the histologic type of growth can be determined frequently from cells contained in the sputum McDonald observed that the squamous type of cancer cell readily and commonly can be found by appropriate technics The oat-shaped cell type is less frequently demonstrated, and the ciliated columnar or goblet cell type is still less often found The failure to find cancer cells in the sputum does not disprove the diagnosis of carcinoma but is of great diagnostic aid

After the appearance of symptoms, if the lesion cannot be completely excised, the duration of life in most cases of cancer of the lung, other than the squamous cell type, varies from 5 to 9 months. The squamous cell tumors usually progress more slowly

Sarcoma of the Lung. Sarcomas of the lung are relatively rare. A provisional classification of pulmonary sarcomas based on anatomic features has been made by Ewing. These features are as follows: (1) diffuse spindle cell type, (2) large round cell variety, (3) peribronchial sarcoma, and (4) lymphosarcoma.

Sarcomas of the lung are divided clinically into the nodular and the lobar types. The nodular tumors may occur as single or as multiple nodules. In the lobar type a large part of the whole lobe or the whole lung is invaded. Pleural effusion, usually of a hemorrhagic nature, often supervenes.

The symptoms of primary carcinoma and sarcoma of the lung are identical.

Asymmetry of the thorax and dilatation of the veins of the thoracic wall, neck or arm may be present Decreased expansion of the lung involved is often relatively early in its appearance The intercostal spaces may be retracted, or if effusion is present or the growth large, they may bulge.

Palpation confirms the irregularities in expansion. Intercostal tenderness may be elicited in some instances Tactile fremitus is diminished in all surface lesions but normal in the centrally located small growths

In the small nodular growths aberrations of the percussion note may not be apparent In massive invasion of the lung there is a flat percussion note, and definite resistance is encountered by the pleximeter finger. In effusions of more than 500 ml of fluid the percussion note over the fluid and tumor is dull, whereas just above the fluid the skodaic area of hyperresonance is sometimes found

On auscultation the characteristic findings consist of either diminished or absent breath sounds and decreased or absent vocal fremitus. Rales may be present but variable accordingly if atelectasis is present. Rales are constant if caused by congestion or bronchitis

The findings elicited by physical means are never definite enough to form the basis of a diagnosis of either sarcoma or carcinoma of the lung. The roentgenologic examination constitutes the most important diagnostic procedure in cancer of the lung Whether or not the cancer of the lung is carcinoma or sarcoma is a diagnosis to be made by the pathologist. This cannot be determined by either the palpating finger or the roentgenologic examination.

Examination of the sputum for malignant cells is repeated, for this is an important and specific diagnostic test Bronchoscopy is of far less diagnostic value in sarcomas of the lung than it is in bronchogenic carcinoma, for it does not often permit of biopsy because sarcomas are usually extrabronchial.

Aspiration biopsy for obtaining tissue for microscopic diagnosis may be considered after an aspiration of effusion has been done, and examination of the fluid on occasion has not revealed malignant cells Aspiration is rarely advisable

DISEASES OF THE TERMINAL RESPIRATORY PASSAGES AND LUNGS

THE RESPIRATORY PASSAGES

The respiratory passages comprise the nose, the nasopharynx and the pharynx The mouth, the larynx, the esophagus, the two eustachian tubes and the two posterior nares open into the pharynx, which thus serves as the common tract for intake of air, food and drink The diseases of the air passages from the external nares up to the pharynx have been described (pp 85 to 96)

The essential anatomic structures for respiration thus begin with this common tract which is provided by the pharynx and extends inward through the larynx, trachea, bronchi, bronchioles and finally the air spaces (atria) and the supporting tissues of the lungs.

Respiration and Its Control. The lungs are part of a mechanism for insuring that the tissues of the body are adequately supplied with oxygen. The functions of the lungs [illegible] with and inseparable from those of the heart and circulation [illegible] ited and presided over by the

A failure of proper respiration may arise, therefore, from defects in the supply or quality of blood to the lung membrane, from defects in the supply or quality of the air, or from defects in the lungs or of their chemical and nervous control

The respiratory center in the brain extends through the upper part of the medulla oblongata and probably into the pons as well. Although one major and two minor centers have been described, it is well to consider the central gray matter as a whole and to think of it as the respiratory "center" acting as a co-ordinated unit. It possesses an inherent rhythmicity, and it controls the activity of the lower motor neurons supplying the respiratory muscles It receives afferent impulses from the lungs via the vagus nerve, and from the aortic arch and carotid sinus via the sino-aortic nerves It is also influenced by impulses coming from the higher brain centers. It is extremely sensitive to certain chemical variations, for instance the carbon dioxide tension or the hydrogen ion content of the blood, and also to the presence of various poisons such as hydrogen cyanide and carbon bisulfide

Some patients who are of a neurotic temperament and full of complaints may respond, during health or during illness, as a result of certain stimuli, physical or emotional, by overbreathing If this is sufficient to reduce the carbon dioxide concentration in the blood, alkalosis ensues and in its turn may be sufficient to cause an attack of tetany. The attack is due to tissue alkalosis and ends spontaneously, as a result of tissue acidosis consequent on the muscular activity of the tetany. Cessation of overbreathing assists in the return to normal conditions. Alkalosis resulting from spontaneous hyperventilation may cause either tetany or effort syndrome.

Defenses of the Lungs. The inhaled air passes over the upper part of the respiratory tract, where it is warmed and humidified The warmed air is drawn through the larynx, trachea and bronchi into the depths of the lungs, where the interchanges of gases can be made with the blood through the respiratory epithelium

Harmful foreign material from outside cannot easily enter, much less remain in, the lower respiratory passages The microbes present in the air may never reach the trachea A large number of them are trapped in the vestibules of the nose, being enmeshed by the hairs which are moistened with sticky mucus, and later ejected by the action of the ciliated epithelium The ciliated epithelium extends over the walls of the nasal sinuses, the greater part of the nasal cavities, the nasopharynx and the back of the soft palate, trachea and bronchi, as far down as the point where the smallest bronchioles expand into the terminal alveoli Mucus is spread in a thin, even, transparent layer

The larynx protects the lower respiratory passages, when need arises, by its sudden reflex closure Such action is observed on exposure to irritant gases such as chlorine.

Soiled mucus collecting in the interarytenoid region may excite the swallowing reflex, and so help to carry off invading organisms to the stomach, where most of them (but not tubercle bacilli) are killed by the acid secretion If the sensitive larynx, trachea or bronchi are sufficiently irritated, the cough reflex is brought into action, thus foreign material is forcibly expelled, a process aided by the shortening and narrowing of the bronchial tubes which is caused by the forced expiration characteristic of coughing

Organisms passing beyond the larynx are subjected to the mucociliary activity in the trachea and bronchi, some may be carried away by lymphatic drainage, but most will be forced back toward the pharynx.

The trachea and its bronchial branches conduct air from the outside atmosphere to the air sacs of the lungs The larger bronchi divide and subdivide, eventually to become bronchioles, devoid of cartilage and mucous glands, but with a muscular coat relatively twice as thick as that of the larger bronchi Each bronchiole ends in a lobule, enclosed in a fibrous capsule with its own supply of blood vessels, nerves and lymphatics The lobule forms, therefore, a fundamental pulmonary unit, and it is the packing together of innumerable such units which, with the conducting tubes, makes up the lung as a whole Inside the lobule the bronchiole divides into still smaller tubes, the terminal branches of which—the respiratory bronchioles—lead into an expanded space (atrium), each atrium leads into two or three air sacs (infundibula) The air sacs are studded with minute finger-like protrusions, the alveoli, which are lined by a single layer of large flattened cells. The air in these alveoli is separated from the blood capil-

laries only by this single layer of cells and the tenuous walls of the capillaries. The alveoli all over the lung are so packed together that any particular capillary lies between adjacent alveoli, so that the blood is in close contact with air on both sides. In the pulmonary meshwork between the alveoli are large numbers of elastic fibers, nerve fibrils and lymphatic channels.

The terminal bronchioles do not possess ciliated epithelium, so that if microorganisms reach this part of the lung they will be sucked into the air sacs during inspiration, and the only defense left is an inflammatory reaction in the alveolar units This is important in the pathology of pneumococcal pneumonia

CYSTIC DISEASE OF THE LUNGS

Congenital Pulmonary Cysts. Congenital cysts of the lungs exist as solitary and multiple fluid or air cysts Fluid cysts have no communication with the bronchus, air cysts have free communication with the bronchus.

The history often reveals a susceptibility to colds and coughs Dyspnea and cyanosis may have been present from the time of birth If severe respiratory difficulties are observed at the time of birth, congenital cystic disease is probable

SYMPTOMS Often the symptoms are manifested as persistent respiratory discomforts which follow an acute attack of bronchitis, whooping cough or pneumonia There is cough, moderate to severe, with expectoration of mucoid to thick purulent sputum. In the interval between these episodes of symptoms the patient enjoys a comfortable state of health if the cyst or cysts do not communicate with the bronchi If the cysts communicate with the bronchi, there is a valvelike constriction at the point of communication, and sudden serious or even fatal dyspnea may develop, for under such circumstances the essential feature is the same as that of a bronchial fistula from any cause

Spontaneous pneumothorax may occur from rupture of the cyst into the pleural space. In the presence of pneumothorax there follow the sudden paroxysmal, respiratory attacks which are associated with signs of tension pneumothorax. The dyspnea is critical, the cyanosis severe, and each convulsive respiratory struggle seems to represent the last act of the patient Thoracentesis may give temporary relief.

EXAMINATION An examination by physical means may elicit the signs of local tympany or suggest a tension pneumothorax There may be a detectable displacement of mediastinal structures and descent of the diaphragm on the affected side

If a young patient has had staphylococcal pneumonia, a radiolucent region in the lung is most likely an acquired cyst A cystic cavity found before any respiratory illness has occurred suggests a congenital cyst Congenital cysts usually maintain a constant size, while acquired cysts or pneumatoceles tend to fluctuate in size. Congenital cysts may have denser shadows (thicker walls) roentgenographically than acquired cysts Infection in congenital cysts becomes a more frequent occurrence as age increases On thoracoscopic examination the lining of a congenital cyst is smooth and glistening while the wall of a pneumatocele is black. Congenital cysts of the lung persist while acquired cysts tend to disappear spontaneously.

DIAGNOSIS Roentgenoscopic examination aided by means of the opaque media is usually diagnostic The diagnosis is suspected from the history and physical examination

The prognosis is good in fluid-filled or air-containing cysts when not complicated by infection or a one-way valve communication with a bronchus.

INFECTIONS OF THE LUNGS DUE TO BACTERIA

Pneumonia. The conditions necessary for the inception of infection for the production of pneumonia are the implantation of virulent microorganisms or ultramicroscopic life in the terminal airways in sufficient numbers that they cannot be immediately overcome by the defensive forces of the host. An obstructio o drain-

age and local irritation or injury to the terminal airways hastens the inceptive processes

The reactions representing virulence of bacteria and host resistance are complex. Regarding the means of passage of bacteria through the mucous membrane, it is known that the absence of ciliary epithelium in the terminal airways aids the infection to become more easily established, for its normal absence in the ductuli alveolares pulmonis (BNA) permits bacterial stasis in these terminal air units In influenzal pneumonia the ciliated columnar cells so situated in the larger air passages are replaced with cuboidal goblet cells, resulting in the impairment of the capacity of the mucous membranes of the larger air passages to dispose of secretions effectively.

In persons who have had an operation or an injury to the thorax, there are often a disturbance of the cough mechanism and interference with movements of the diaphragm and of the accessory muscles of respiration, and these are major mechanical factors in allowing pathogenic agents to enter the pulmonary parenchyma

In these patients the local irritation and injury are supplied by an inability to get rid of the secretions In the presence of these irritations and injuries a virulent bacterium which is present as a part of an acute respiratory infection at the time of operation and injury often can originate pneumonia

A pneumococcal infection in a particular instance depends on the individual susceptibility to the pneumococci with which the patient comes in contact, provided the pneumococci possess sufficient virulence to produce disease.

The pneumococcus with its type specific polysaccharide capsule when introduced into the body of the host is capable of stimulating defensive mechanisms The immune substances include agglutinins, precipitins, opsonins and protective antibodies. Antibodies to pneumococci can be demonstrated in a large percentage of human beings It is assumed that the antibodies thus found in normal persons are the result of previous exposure to pneumococci, that is, of latent or manifest infection Normal carriers probably represent those who respond well to pneumococcus antigens and are, therefore, highly resistant to infection

The carrier state and the dosage and virulence of organisms received by the host are important factors in the production of pneumonia Equally important factors include the lowering of resistance of the individual by exposure, chronic disease, inanition and alcoholism Depression of protective mechanisms of the mucous membranes of the upper portion of the respiratory tract by viral and other infections is important

Pneumococcal Lobar Pneumonia The pneumococci are of the tribe Streptococceae and family Lactobacteriaceae They are gram-positive, frequently of lancet shape, usually arranged in pairs or short chains, and possess an easily demonstrable capsule

Of some 75 types of pneumococci, the 32 types commonly described as causative agents of pneumonia vary considerably in distribution Types I, II, III, V, VII, VIII and XIV are the most frequent in pneumonia Types I, II, and V usually are associated only with lobar pneumonia and are present in carriers only when the carriers have been in close contact with patients ill with lobar pneumonia In a series of 13,160 cases of pneumococcal pneumonia as recorded by Rosi, the types of pneumococci in order of prevalence were I, II, III and VII Pneumococci associated with healthy carriers are usually type III, and are present in one fourth to one half of healthy persons The consensus is that type III pneumococci are capable of causing pneumonia only in those who are debilitated or aged Type VI rarely provokes infection

PATHOLOGY The progress of the pneumonic process has been divided into three stages (1) engorgement, (2) red hepatization, and (3) gray hepatization The initial

before the whole lobe is involved It is thus revealed how it is possible to have engorgement, red hepatization and gray hepatization present in the same pneumonic lobe of the

lung Resolution occurs as the affected tissue becomes soft and friable. As the pneumonic process resolves, only a small part of the exudate is expectorated; the major portion is autolyzed by enzymes supplied by the degenerating leukocytes and macrophages and is resorbed

The incubation period ranges from a few hours to 1 or 2 days.

SYMPTOMS The onset of lobar pneumonia is characterized by a chill, fever, stitch in the side, nausea and vomiting The chill is often prolonged and is followed by a headache and generalized body aches. The temperature rises rapidly to 104 to 105 F (40 to 40 5 C) Very soon there is a short unproductive cough The cough is restrained because it enhances the pain. The pain is sharp and stabbing, and its presence seems to cut the cough short In rare instances the pain is absent. The face is red and the cheeks are flushed, often the cheek on the affected side is more flushed than the opposite cheek. The expectoration at first is scanty; it becomes blood streaked and then brownish, yellow or red in appearance The expectoration increases as the engorgement of the lung and the cyanosis increase.

The degree of cyanosis is somewhat of an index of the severity and extent of the pneumonic process Dyspnea and hyperpnea compensate only in part for the cyanosis, which is due to anoxemia dependent on alveolar edema and exudate which make impossible a free exchange of oxygen and carbon dioxide.

The pulse rate is increased, usually in proportion to the increase in temperature Circulatory failure, if it occurs, is not primarily myocardial in origin, but is more nearly related to circulatory collapse of the vascular capillary bed A sudden decrease in the blood pressure observed during the course of pneumonia is related to the tachycardia, prostration and dyspnea This evidence of circulatory strain in pneumonia is likely to occur more frequently in the obese, the alcoholics and the aged

A pneumonic crisis may occur within one day after onset or it may be delayed for two weeks or more The crisis is uncommon before the third day and rare after the twelfth A precritical rise, of a degree or two, of fever may occur Then within a period of from 5 to 12 hours the temperature returns to normal (often a fall of 6 to 8 F). After the crisis, the temperature is often subnormal, sweating is abundant and the patient falls asleep for several hours

There are all gradations of severity of lobar pneumonia In fulminating pneumonia there are prostration, shocklike reaction, and often pulmonary edema (wet pneumonia) These patients may die within a few hours from circulatory collapse In contrast, there are those who have fever of brief duration with crisis within 24 hours (abortive pneumonia) Ambulatory cases occur in which the course is mild and in which the lesion is detected on roentgenologic inspection only. Central pneumonia with location of the lesion near the hilus of the lung will often give no signs on physical examination However, within a few days physical signs will appear The involvement of one or more lobes on each side of the thorax has been referred to as double pneumonia, in which the prognosis is less favorable than with involvement of a single lobe In a massive pneumonia the bronchi of the involved region are often filled with exudate, and the physical findings may simulate pleural effusion In migratory pneumonia the process extends through the lobes of one or both lungs. In lethal instances of the disease in which there was little or no evidence of involvement of neighboring lobes detectable prior to death, necropsy frequently reveals such extension.

EXAMINATION. On examination the face, neck and hands are hyperemic or cyanosed. Dyspnea is present, and there is often a herpes labialis and a flushed cheek on the side of the lesion The respirations are increased at intervals to several times their normal rate. After consolidation has occurred, unless the bronchi are filled with thick secretion or fibrinous exudate, or unless pleural effusion is present, the vocal fremitus over the affected portion of the lung is increased and a friction

fremitus also may be felt If the consolidation is deep-seated, the resonance may be impaired or no changes can be elicited on percussion. The vocal fremitus, if the larger bronchi are not plugged, is increased

In the early stages the breath sounds are often enfeebled and may be suppressed. When the breath sounds are present at the end of inspiration, crepitant rales may be heard As engorgement advances into consolidation, the breath sounds become bronchovesicular and then bronchial in type.

The occurrence of persistent crepitant rales in the presence of systemic reaction, cyanosis and dyspnea—any one of which alone is significant—together is almost diagnostic of pneumonia A limitation of expansion on the affected side and pleural friction rubs are often present Impairment of resonance appears or increases in intensity with consolidation If the region of consolidation is small, its detection and delineation may best be facilitated by the increased intensity of tactile fremitus The demonstration of increased tactile fremitus depends on the extent of the involved space at the periphery and the experience and tactile sense of the examiner. If a bronchus becomes plugged by secretions, the atelectasis and absence of breath sounds with some impairment of resonance may be difficult to interpret until sudden clearing of secretions after cough or a change in position is made.

Sputum and blood for cultures should be obtained before chemotherapy is started The determination of the presence or absence of invasion of the blood stream is valuable in every case Streptococci or staphylococci or other organisms may prove to be the etiologic agent and their recognition is more important for therapeutic application than the type of pneumococci The presence of such organisms as Friedländer's bacillus or *Hemophilus influenzae* may be suspected from Gram's stains The susceptibility of the invading organisms to the various chemotherapeutic drugs as well as to the antibiotic agents has made the determination of these susceptibilities a standard procedure for the proper therapeutic results

Leukocytosis is the rule in pneumonia The usual counts vary from 15,000 to 25,000 per cubic millimeter of blood Increased leukocytosis may be present with complications such as empyema or pulmonary abscess. Reduction of leukocytes occurring with extension or complications, or at any time during the course of the disease, indicates an undesirable response and a low resistance to the disease.

Diagnosis Cyanosis, hyperpnea, dyspnea, fever and chills occurring in a previously well individual and attended by physical and roentgenologic evidence of pulmonary consolidation are distinctive of lobar pneumonia. In the presence of an acute exanthem, meningitis, or other severe systemic disease lobar pneumonia is not diagnosed until evidence of localization becomes apparent. Such localization as well as the extent of the pneumonia is more precisely located by means of roentgenologic examination

The early involvement of the pleura in the lower portion of the right lung field may cause referred abdominal pain This pain may simulate the pain of cholecystitis or appendicitis, so that time may be required in order to make the correct diagnosis

The organism producing the lobar pneumonia is determined by bacteriologic methods

In regard to the prognosis in pneumococcal pneumonia in recent years, two groups of patients who had this disease were studied by de Beradinis and de Andino. The first group of 75 patients was admitted during the period of 1937 to 1940. The second group consisted of 91 patients admitted during the period of 1946 to 1949 Comparison of the two groups showed that there was no decrease in the rate of admission of patients with pneumococcal pneumonia. In the years 1946 to 1949 there was an increase in incidence of the disease in higher age groups, with an increase in mean age from 39 9 years to 46 6 years There was also an increase in the occurrence of pneumococci of type IV and above with a corresponding fall in lower numbered types, especially type I Physical observations of lobar con-

solidation were made in 63 patients of the first group as compared with 35 in the second group. The percentage of septic complications fell from 16 to 7.7 per cent, probably as the result of antibiotic therapy. The over-all mortality rate fell from 21.3 to 6.59 per cent The majority of the patients who died had the complicating features of chronic degenerative disease, which influenced the mortality rate unfavorably in patients aged more than 40 years.

COMPLICATIONS. Empyema and pulmonary abscess are the commonest complications Empyema is suspected if there are (1) a lysis instead of a crisis of the fever, (2) recrudescence of fever, (3) a continuance of the increased leukocytosis, (4) sweats and a progressive inanition, and (5) the physical or roentgenologic evidence of free or encapsulated pleural effusion.

Delayed resolution, bronchiectasis, pulmonary fibrosis, pericarditis, meningitis, endocarditis, hepatitis, parotitis and purulent arthritis are of rare occurrence when sulfonamide or antibiotic therapy is employed

Bronchopneumonia. Bronchopneumonia is a diffuse process not often caused by the pneumococci. It is not lobar in distribution. A bronchial pneumonia differs from the so-called atypical pneumonias by the fact that etiology can be determined The disease most frequently is caused by beta-hemolytic streptococci Other causative organisms are *Hemophilus influenzae*, *Staphylococcus aureus*, gram-negative micrococci, and *Streptococcus viridans* Bronchopneumonia in adults is usually secondary to an acute infection of the upper part of the respiratory tract, influenza, measles or chronic disease It tends to be most frequent in early and late life.

SYMPTOMS Since bronchopneumonia is almost always secondary to a preceding illness, the symptoms are merged with those of that illness. The initial symptoms of bronchopneumonia are fever, cough and dyspnea. Rusty sputum is less frequent than in lobar pneumonia There may be a chill or a chilly sensation Pain develops immediately The fever is of the irregular, daily, fluctuating type. Prostration and signs of anoxemia vary considerably and while they tend to be less in bronchopneumonia than in lobar pneumonia, nevertheless a marked cyanosis may develop which is indicative of a severe process The symptoms of the disease may fail to have a respiratory localization, and thus there may be no respiratory symptoms Whether or not there are respiratory localization and symptoms, the fever tends to terminate by lysis. The duration of the disease is exceedingly variable and all symptoms may merge into those of a complication Complications are less frequent in bronchopneumonia, however, than in lobar pneumonia

The presence of acute respiratory symptoms and fever in a patient who has had influenza, measles or any respiratory infection which has reached epidemic proportions is accepted as pneumonia bronchial in origin until proved not to be of such origin

EXAMINATION. The physical examination reveals findings varying from those present in acute bronchitis to those of lobar pneumonia At times bronchopneumonia may involve almost an entire lobe of a lung. The presence of several localized re-

[illegible]

sounds.

DIAGNOSIS. A history of previous respiratory infection, physical signs and roentgenologic evidence in the thorax are conclusive

When bronchopneumonia occurs secondary to chronic disease, particularly in the advanced decades of life, high mortality rates are expected Following epidemics of measles, respiratory infection and influenza, a high mortality rate is the rule Increasing age, marked extent of pulmonary involvement, bacteremia, alcoholism, inanition and debilitating disease are all factors making for grave prognosis

Postoperative Pneumonia. This disease is bronchopneumonia occurring soon after a surgical operation. The predisposing causes of postoperative pneumonia (bronchopneumonia) are listed by Whipple as follows: (1) inflammations in the upper part of the respiratory tract present at the time of surgical operation; (2) vasomotor changes causing a congestion of the pulmonary vessels; (3) factors, during and after the operation, which inhibit the normal thoracic and abdominal respiratory movements and favor atelectasis and hypostasis in the lung; (4) local or general infections elsewhere than in the respiratory tract; (5) a lowered natural or acquired immunity to organisms which can incite pneumonia, and (6) increase in the virulence of the inciting organisms, for instance the presence of a virulent strain of streptococci causing endemic sore throats.

Postoperative pneumonia often begins as atelectasis with pneumonia developing in the collapsed portion of lung. The symptoms are those of bronchopneumonia. The onset of symptoms may be as early as the second postoperative day or delayed until the patient is out of bed The physical findings are likewise those of bronchopneumonia

The bedside roentgenologic examination is used as guesswork for diagnosis until the patient is able to be moved for physical examination and the regular roentgenologic examination

Post-traumatic Pneumonia. Thoracic injuries, especially fractured ribs which cause interference with respiration, are frequently associated with pneumonia. Interference with respiration appears to be the most important single factor in the occurrence and localization of pneumonia or atelectasis in post-traumatic as well as postoperative patients Interference with respiration also accounts for an occasional pneumonia after severe head injuries.

The etiologic agent in post-traumatic pneumonia is often a pneumococcus A rib fracture in an elderly person followed by infection with pneumococcus type III may have a serious prognosis Streptococci, staphylococci or other organisms are often the causative microorganisms and they too cause a serious pneumonia in a patient of any age

The symptoms are often obscured by those of the original injury The expectoration of blood often indicates a pulmonary hemorrhage A fever and leukocytosis associated with respiratory distress and hemoptysis are significant manifestations.

Following trauma, intrapulmonary hemorrhage may be the cause of physical signs like those associated with bronchopneumonia The physical signs after trauma are usually scattered with only at times those of consolidation of a lobe.

A presumptive diagnosis can be made if there are no evidences of intrapulmonary hemorrhage on roentgenologic examination

Prognosis is variable, depending on the resistance of the host in relation to age, chronic disease, alcoholism and the virulence of the invading organism

Pneumonia Due to Unusual Bacterial Agents. Infrequent agents causing pneumonia include bacilli such as *Hemophilus influenzae, Hemophilus pertussis, Bacillus pyocyaneus* (*Pseudomonas aeruginosa*), *Bacillus anthracis* and *Pasteurella pestis*, cocci, such as *Gaffkya tetragena*, meningococci and *Neisseria catarrhalis.* Pneumonia may also be associated with brucellosis, typhoid fever, diphtheria and rickettsial diseases

Acute Pneumonitis. The term acute pneumonitis is used by Adamson (in Myers and McKinlay) to indicate acute inflammation in the lung that is not only endobronchial but involves the parenchyma as well. The parenchymal involvement in acute pneumonitis is not sufficient to produce signs or symptoms of pneumonia The term thus includes many separate etiologic entities; yet if the definition of the term, as it is given by these authors, is adhered to, the underlying pathologic condition is definite and precise.

Adamson has arranged a convenient classification of pneumonitis which is essentially as follows. (1) common cold pneumonitis, (2) influenzal pneumonitis, (3) obstructive pneumonitis, (4) *exacerbation pneumonitis.*

1 **Common Cold Pneumonitis.** Gross pulmonary infiltration is found on roentgenologic examination of the thorax in many patients who have insignificant symptoms Often there is a history of a common cold or slight infection in the upper part of the respiratory tract A follow-up on these patients shows complete resolution in the course of a few weeks

Physical signs are usually absent

2 **Influenzal Pneumonitis.** The pneumonitis following influenza is essentially inflammatory, and that following infection of the upper part of the respiratory tract is *commonly obstructive In most instances of influenza the respiratory symptoms* commence after the first day after the onset, whereas in infections of the upper part of the respiratory tract the inception is with respiratory symptoms

Influenza is characterized by the sudden onset of headache, muscle pains, anorexia, chilliness, weakness, depression and general malaise If there is a localization of the discomfort, it is the backache and aching legs There may be signs or symptoms of respiratory inflammation varying from pharyngitis to pneumonitis or in some a definitely manifested pneumonia

There is a widespread bronchitis accompanied by retrosternal pain, and a *burning*, dry, *harassing* cough *with* scanty *sputum There may be coarse rhonchi* diffusely spread throughout both lungs Crepitations after coughing are commonly found about the bases which indicate definite parenchymal infiltration

On roentgenologic examination of the thorax there is a peribronchial infiltration which spreads out into the parenchyma from one or both roots The commonest site is in the medial half of the base, the cardiophrenic angle being frequently involved The extension may be into the middle third and not infrequently into the upper lobe In most cases the involvement is unilateral, but both lower lobes may be involved at the same time or in sequence Migration from place to place is common

Characteristically, influenza does not produce leukocytosis, and if the total leukocyte count is more than 10,000 per cubic millimeter, the pulmonary infection is due to or complicated by some pyogenic organism The common occurrence of *a relative bradycardia in influenza is of value in the recognition of influenzal* pneumonitis.

3 **Obstructive Pneumonitis ("Infection Atelectasis").** An obstructive pneumonitis may arise when there is an abnormal respiratory secretion It is characterized by sudden onset of pleural pain in the axillary line associated with shortness of breath Constitutional signs are mild or absent The physical and roentgenologic signs are those of pulmonary collapse, elevation of the diaphragm or displacement of the mediastinum

This condition requires treatment primarily directed to relief of obstruction

4. **Exacerbation Pneumonitis.** Pulmonary tissue damaged by previous inflammation may have as a consequence *an impairment of natural drainage* Reduced natural drainage is conducive to accumulation and stagnation of secretion and retention of infected material As the result of poor drainage local inflammation occurs which is a pneumonitis A variety of clinical effects may be produced, depending on the relative participation of the two factors, obstruction and inflammation, and the extent of the process

There is a history of colds, cough and purulent expectoration In a few cases there is the history of attacks with pain and fever. In the intervals between attacks the patients are free from symptoms, or chronic cough may persist The attacks are always *localized* and repeated in the same side

The physical signs and roentgenologic findings during any such attack are similar in a general way to those of any other form of pneumonitis

There may be signs of chronic infection enough to suggest chronicity. Such signs are clubbing of fingers, thoracic asymmetry, reduced movements, dullness or coarse rales which do not clear after coughing

Roentgenologic observations may suggest chronic rather than acute changes.

Pulmonary Abscesses. In a patient in whom the presence of a pulmonary abscess is suspected, the history of a surgical operation, particularly on the mouth, nose or throat, or of a recent attack of pneumonia is significant. Pulmonary abscesses may follow surgical procedures which are prone to give pulmonary infarcts, such as operations on the pelvis and hernial repairs They may occur during the course of a septicemia such as endocarditis or furunculosis. History of an attack of choking while swallowing food, or an attack of cough following aspiration of some other object, is significant from the standpoint of abscess due to foreign body In some patients who have pulmonary abscesses there is no history of pre-existing conditions such as those just mentioned. This is particularly true of pulmonary abscesses in children following aspiration into an air passage of a foreign body which supposedly was coughed up

The pyogenic abscess is usually caused by the pneumococcus, *Staphylococcus aureus*, and the hemolytic streptococcus Anaerobic organisms which normally inhabit the

can produce lung abscesses

A pulmonary abscess may arise from an infected embolus causing infarction, and secondarily abscess formation In other instances lodging of a sterile embolus produces infarction, organisms are aspirated from the mouth, nose and throat and infect the infarcted region in the lung, and thus an abscess is formed In some instances both processes are present, namely, an infected embolus and the aspiration of infected material from the nose, throat and trachea

The prime factor which favors the chances of abscess formation after operations on the nose, mouth or throat is the use of general anesthesia for the operation. The general anesthesia abolishes the cough reflex and thus permits aspiration of infected material from the upper air passages

Pulmonary abscesses often result from the aspiration of foreign bodies into a bronchus Abscesses due to aspirated foreign bodies are more frequently found in the lower lobes, especially the right Once the foreign body is lodged in the bronchus, it ulcerates through the wall of the bronchus into the pulmonary tissue, and abscess formation ensues The object for abscess formation may be of intrapulmonary origin, for instance, Vinson called attention to calcifications produced by the first infection type of tuberculosis in hilar lymph nodes which ulcerated into bronchi and were aspirated into their ramifications, causing abscess Other causes of pulmonary abscess are obstruction of bronchi by tumors and pneumonia.

SYMPTOMS A chill followed by fever similar to that observed in pneumonia may be the first manifestation of pulmonary abscess In the beginning of the disease cough and expectoration are slight or absent As the condition progresses, the cough begins and increases in severity Pleural pain and the sudden expectoration of a quantity of sputum with a foul odor are common manifestations. Abscesses which follow operations and aspirations from the mouth and throat usually are of sudden and severe onset There are profuse sweating and prostration Pulmonary abscess does occur with less severe initial symptoms, being manifested only by a general aching of the body and malaise Spitting of blood, varying in amount from streaks in the sputum to fatal hemorrhage, occasionally occurs even in those who have mild symptoms The symptoms of multiple abscesses due to septic emboli often are masked by the symptoms of the main disease. During the course of septicemia or pyemia the first symptoms of a pulmonary abscess or abscesses may be

thoracic pain, cough and expectoration. No one symptom or combination of symptoms is pathognomonic of pulmonary abscess since all may be caused by other diseases.

EXAMINATION Inspection often reveals clubbing of the fingers and toes, sometimes within a few weeks after onset of the abscess. Hypertrophic pulmonary osteoarthropathy develops in some instances. Limited movement of the thoracic wall on respiration often occurs on the affected side, and the phrenic wave sign is decreased or absent If the abscess has an acute severe onset the patient appears seriously ill

If the abscess is small, no abnormal signs are elicited by palpation If the abscess is large, with extensive inflammation of the adjacent pulmonary tissue, tactile fremitus is increased except in the presence of pleural exudates, when it is diminished or absent The reflex protective mechanism consists of a rigidity of thoracic muscles which can be elicited and palpated by tapping on the chest over the affected area with the end of the stiffened fingers.

The percussion note is normal if the abscess is small, but when it is large and near the surface, a dull to a flat sound is elicited Over large cavities near the surface of the lung a tympanitic sound may be heard when the cavity or cavities are empty

On auscultation the breath sounds are normal if the region of disease is small, but as it becomes larger, bronchial breathing appears. If large cavities are near the surface and are partially or totally empty, amphoric breath sounds may be heard Changes in the spoken and whispered voice sounds depend on the extent and situation of the disease Voice sounds are normal when normal lung tissue is superimposed over the abscess but are heard distinctly over the areas where bronchial breathing is elicited, and if large empty cavities exist, pectoriloquy may be present Rales are usually heard when the region of disease is large and near the surface These may be consonating if cavities are only partially filled

DIAGNOSIS The foregoing symptoms and physical signs may be definite enough for the purpose of diagnosis, when interpreted and correlated with the history.

Roentgenologic examinations often determine the location and extent of gross disease, although some abscesses are not located by this means. Large abscess cavities, when completely filled with pus, present no fluid level; their outlines may not be seen, so that their presence is not detected on roentgenologic examination. If evacuation of the abscess cavity or cavities, as by postural drainage, can be accomplished, then iodized oil can enter, after which the roentgenogram affords good evidence as to size and location of cavities Endoscopic inspection of bronchi should always be made if there is doubt as to either the presence or the etiology of an abscess

Pulmonary abscesses may occur in tularemia, brucellosis and amebiasis. Inasmuch as tuberculosis may coexist, a search is made for tubercle bacilli and if there is doubt, guinea pig inoculation is performed

A single abscess may heal spontaneously in 1 of every 4 cases In the remaining 3 cases the prognosis is guarded The poor prognosis in many is due to conservatism and the lack of surgical skill Spontaneous recovery rarely occurs if the disease is allowed to persist more than a few weeks Surgical treatment as soon as the diagnosis is made markedly improves the prognosis

Pertussis (Whooping Cough) The genus *Hemophilus pertussis* (whooping cough bacilli), type *Hemophilus influenzae*, belongs to the family of Parvobacteriaceae

Strains of *Hemophilus pertussis* on primary isolation constitute a single antigenic type. They are gram-negative. The organisms can be identified serologically by the agglutination test

The distribution of pertussis is cosmopolitan The disease is endem[illegible] ies

occur at intervals of two to four years in the more thickly populated areas, beginning in winter, or spring, and lasting throughout the summer months In the South the disease spreads during April and May, in the North January and February are the peak months. Pertussis is distinctly a disease of early life except in some women, particularly in the older age groups Infants less than 6 months of age are especially susceptible, and among them the disease has a higher mortality. The communicability rate is high, particularly in family exposures in which it is from 75 to 90 per cent.

IMMUNITY. Although an attack usually confers lasting immunity, second attacks do occur.

Active immunity against the disease can be induced by the injection of an antigenic strain of the organisms Passive protection may be given to an infant by the injection of convalescent serum, hyperimmune human serum, or immune rabbit serum. It is not generally transferred transplacentally but can be produced in this manner by actively immunizing the pregnant mother during the third trimester of pregnancy.

A profuse catarrhal inflammation of the epithelium in the larger air passages is always present. Purulent exudate and an excess of mucus accumulate in the lumina of the smaller bronchi and bronchioles. Peribronchiolitis is common, extending from the hilus outward along the blood vessels which accompany the bronchi to the middle or outer portions of the lungs.

The tracheobronchial lymph nodes are usually enlarged during the active and early convalescent stages of the disease and produce the characteristic hilar lesion commonly observed on roentgenologic examination

In addition to the pulmonary lesion produced by *Hemophilus pertussis,* secondary invading organisms may cause purulent bronchitis, and even lobar pneumonia Bronchiectasis may develop early in the course of the disease but it is commoner as a sequela Emphysema is almost always present, blebs on the surface of the lung being observed in practically all cases in which death ensues Changes in the brain are described as circulatory, degenerative, and inflammatory Meningitis and encephalitis result from inflammation

SYMPTOMS The incubation period is from 10 to 14 days. The clinical course consists of three stages the catarrhal, paroxysmal, and convalescent; each lasting approximately 2 weeks Spasmodic coughing may occur for several weeks or months longer

The first symptom commencing with the catarrhal stage is a mild nocturnal cough, which soon becomes diurnal The cough develops as that of a bad cold, but the appetite fails as the cough increases in severity, and there is a suffusion of the conjunctivae with edema of the lower eyelids.

Toward the end of the second week the paroxysmal stage commences The cough becomes a series of explosive efforts of violent expiratory coughs during which inspiration is impossible Finally inhalation is performed through a markedly spastic larynx, and there is a rather loud, high-pitched inspiratory noise called the whoop During the period preparatory to the whoop and soon thereafter the veins of the neck and forehead are prominent, the face becomes congested and cyanotic, and mental confusion results In infants the characteristic whoop may not occur, but choking, cyanotic attacks are common

The convalescent stage commences after a month of coughing, and the paroxysms diminish in frequency and severity The appetite improves If a cold develops during convalescence, all the symptoms may reappear and continue for several weeks more if a superimposed bronchitis remains active

Pertussis may be extremely mild and may last only a few days without definite paroxysms, whoop, or vomiting

At any time during the course of the disease complications may supervene and the symptoms and physical findings are accordingly changed

Bronchopneumonia is a serious complication Atelectasis, bronchiectasis, pulmonary fibrosis, and emphysema, either vesicular or interstitial, develop in many instances when the disease is severe Pneumothorax and empyema may occur

Subcutaneous emphysema occurs when air from ruptured surface blebs escapes by way of the mediastinum into the tissues of the neck and thorax. In whooping cough, in contrast to spontaneous pneumothorax, subcutaneous edema is a serious complication and implies a fatal outcome.

Convulsions are most commonly limited to infants Encephalitis, epilepsy, mental retardation, visual defects, temporary paresis and hemorrhages of the brain are described

Secondary mechanical effects attributed to the strain of coughing are conjunctival hemorrhages, epistaxis, ulcer of the lingual frenum, intussusception, hernia and rectal prolapse Often as the result of coughing in adolescents there is soreness of the muscles of the lower part of the thorax and particularly of the upper part of the abdomen

EXAMINATION. The findings on examination by physical means depend on the stage of the disease and the presence or absence of complications when the patient is examined During the course of mild to moderate degrees of severity of the disease there may be very few or no significant physical findings. In the severe instances of the infection there are various sorts of rales throughout both lungs The presence of crepitant rales in any part of the lung often signifies the onset of a bronchial pneumonia in the region where the rales are present

A *progressive increase in the total leukocyte count occurs* during the late catarrhal or early paroxysmal stage These cells may increase to 15,000 to 45,000 per cubic millimeter of blood as the result of lymphocytosis

DIAGNOSIS A history of definite exposure is of much diagnostic value A modified type of the disease may be expected when vaccination fails to protect completely

Hemophilus pertussis may be isolated by cultures from the respiratory tract. During the catarrhal period positive cultures may be expected in from 70 to 90 per cent of the cases.

The diseases which may produce symptoms simulating those of pertussis are infection of the adenoids or nasal sinuses, allergic reactions, and infection of the trachea with *Hemophilus influenzae*. Parapertussis resembles mild pertussis and can be differentiated only by culture

The mortality rate is about 25 per cent during the first year of life and 10 per cent during the second year The disease is seldom fatal after the fifth year.

Hemophilus Parapertussis (Bacillus Parapertussis). *Hemophilus parapertussis* is a short, ovoid, gram-negative, nonmotile bacillus which in many respects resembles *Hemophilus pertussis* It is the cause of parapertussis, a disease which resembles mild pertussis, from which it can be distinguished only by bacteriologic methods

The incubation period of the disease in man is from 6 to 15 days The onset is similar to that of whooping cough, but may be more abrupt The cough is less severe than that of whooping cough, but is spasmodic, and is sometimes followed by a whoop Vomiting is less frequent than in whooping cough. The entire course of illness is from 1 to 3 weeks The disease often resembles tracheitis

It is not known whether one attack of parapertussis confers lasting protection An attack of parapertussis *does not confer immunity against pertussis*, nor does an attack of pertussis confer protection against parapertussis.

Pulmonary Tuberculosis. *Primary Phase.* In the majority of those who have pulmonary tuberculosis there is a known exposure to the disease. In children often the exposure has been prolonged. Prolonged exposure to contagious tuberculosis is not necessary for the acquisition of a sufficient number of tubercle bacilli to become infected, for an exposure of seconds of time under proper conditions may be adequate for the transfer of large numbers of organisms

Tuberculous infections are divided into the primary phase, or the first infection, and the secondary or reinfection tuberculosis.

The National Tuberculosis Association defines the primary phase of a tuberculous infection as the pathologic processes which follow directly and uninterruptedly the first implantation of tubercle bacilli.

In the first infection by tubercle bacilli the organisms gain entrance through the nose, mouth, eyes, abrasion of the skin or through the genital tract. The bacilli are phagocytosed by neutrophilic cells After the bacilli are in these cells, they may be inactivated or deposited in the tissues and are thus focalized These neutrophilic cells containing tubercle bacilli may enter the blood and may be carried about in the blood stream to lodge in those parts of the body most richly supplied with fine capillaries. Thus lesions may be originated as focal disease in the lungs, bones, joints, lymph nodes and meninges

The first infection of tuberculosis usually is caused by inhalation of tubercle bacilli. The primary infection focus consists of a small tuberculous pneumonia often situated in the lower parts of the upper lobes, or in the upper parts of the lower lobes, near the pleura The center of the focus undergoes caseation rapidly (parenchymal focus) As caseation proceeds, tubercle bacilli are liberated and carried through the lymph channels to the regional bronchopulmonary lymph nodes

The primary complex heals promptly. However, in children exposed to prolonged infection it may not heal A failure to heal may result in a parenchymal lesion which may ulcerate into a bronchus and permit of bacillary dissemination through the bronchial system The primary hilar lymph-node foci may ulcerate into an adjacent bronchus, and cause a fatal tuberculous bronchopneumonia.

SYMPTOMS In the first infection type of tuberculosis, the symptoms simulate a bad cold or influenza The febrile reactions of this type of tuberculosis are of short duration, usually lasting not longer than 10 days or 2 weeks The temperature ranges between 99 and 101 F (37 2 and 38 3 C)

It is only when the primary infection fails to heal, and forms a parenchymal pneumonia which ulcerates into a bronchus, or when the hilar lymph nodes ulcerate into a bronchus, that the primary infection causes a serious disease such as a bronchopneumonia These primary bronchopneumonias may cause death The serious manifestations of a primary infection may occur at any age and are not limited to children.

EXAMINATION In the usual instance of first infection tuberculosis the physical examination is of no value in the detection of the tuberculous process in the lungs of children or adults

It is usually stated that when healing of the primary complex occurs, two signs are left The first sign comprises the lymph-node foci which partially or entirely heal and become calcified Even though calcification has occurred in the lymph nodes, viable tubercle bacilli may remain The second and the most definite sign left to indicate the presence of the primary complex is the fact that the body has become allergic to tubercle bacilli or their metabolic products, which can be demonstrated by positive tuberculin reactions

Positive findings on roentgenologic examination are present in but a few of those who are affected with a first infection type of tuberculosis.

Several years after the first infection type of tuberculosis, there may appear on the roentgenograms sharply outlined shadows in the pulmonary parenchyma or the hilar region which represent dense deposits of fibrous tissue, calcium or bone as the result of first infection tuberculosis This is a Ghon lesion or complex.

Tuberculosis as the cause of calcification in the lungs and hilar region is responsible in only one-half the instances in which calcifications are visualized by roentgenologic examinations (see Calcifications of Lungs, page 617).

Reinfection Phase. Following the advent of the primary infection with pulmonary tuberculosis a latent period intervenes. This latent period may last indefinitely if reinfection does not occur The latent period is the time supervening between the primary infection and the reinfection and the development of symptoms from the reinfection

The sources from which the reinfection is derived are always listed as exogenous and endogenous reinfections The exogenous source is from anywhere that live virulent tubercle bacilli may be obtained.

There are four sources of *endogenous* reinfection: (1) a primary pulmonary focus of the lung may break down and discharge bacilli into other parts of the lungs; (2) a caseated primary regional lymph-node focus may rupture into a bronchus, causing a tuberculous aspiration bronchopneumonia; (3) an active primary regional lymph-node focus, situated inside or outside of the lung, may send tubercle bacilli to the lung or other parts of the body by way of the lymphatics and the blood stream, (4) small apical foci which have developed as a result of early hematogenous dissemination frequently become progressive, ulcerate, and discharge bacilli into the bronchi.

Three forms of tuberculosis are discussed here

1 ***Miliary Tuberculosis.*** Miliary tuberculosis is caused by the discharge of the contents of a tuberculous lesion into either the blood or the lymph streams Hematogenous dissemination may occur during the active phase of the primary infection type of tuberculosis or as a terminal miliary spread in the reinfection type of the disease It is commoner in those who have not had symptoms of tuberculosis than in those who have had symptoms.

Many of the tubercle bacilli that reach the blood stream are filtered out by the lungs, kidneys, peritoneum, bones and the central nervous system. However, in 4 cases of each 5 the main localization is in the lungs due to the extent of the capillary bed here

The symptoms commence with weakness, malaise and fever, which increase in severity. The temperature ranges from 101 to 104 F (38 3 to 40 C) The respiratory rate is normal at first but increases, and cyanosis of a marked degree develops in the late stage of the disease. Cough is slight in the beginning but becomes distressing as the fever and cyanosis develop The sputum is scant

On examination the patient appears seriously ill Results of examination of the thorax by physical means are negative Roentgenologic examination of the thorax usually is not helpful in the beginning of the disease Ophthalmoscopic examination may reveal the presence of tubercles in the retina

In the presence of a more continuous fever, a greater failure of health, a more rapid loss of weight, and a more severe weakness in a patient known to have tuberculosis, a presumptive diagnosis of miliary tuberculosis can be made In all others, signs of localization, usually in lungs, must be awaited. Tubercles may be found in the retinae and may be the first definite diagnostic sign. Often in severe fulminating instances of the disease the diagnosis is not made during life except in those known to have tuberculosis. In the late stage, in approximately one-half of those who have miliary tuberculosis, a large number of small shadows appear in the roentgenograms of the lungs, and may be the first definite diagnostic finding

2. ***Tuberculous. Pneumonia (Galloping Consumption).*** A tuberculous pneumonia may result from a lesion of the primary phase eroding into an air passage and discharging its contents into the lumen A discharge of the tubercle bacilli into the bronchi may originate from a chronic reinfection type of lesion and cause a pneumonia. Occasionally a small focus of either the primary phase or the reinfection type of the disease may rupture into a blood vessel so that he bacilli

are disseminated into that part of the lung which this vessel supplies. This may involve a part of a lobe, a whole lobe, or an entire lung. When large regions of pulmonary tissue are affected, the hypersensitiveness caused by the tuberculoprotein aids in a necrosis of the tissues and a rapid development of pulmonary cavities

SYMPTOMS The disease frequently occurs in those who seemingly have been in good health. At the onset the symptoms are those of lobar pneumonia or of bronchopneumonia In some instances the onset is sudden, commencing with chills, high fever and pain in the thorax.

The onset may be more slowly progressive, with cough, fever, aching of the body, anorexia and malaise These symptoms soon begin to be more severe There is a rapid loss of body weight and the cough is severe. Sputum appears, increases in amount, is yellowish or greenish and streaked with blood, often profuse hemorrhages occur

EXAMINATION The patient is seriously ill The cheeks are flushed and sunken and the eyeballs are soft and retracted. The respirations are increased, profuse sweating and chills are regularly observed

On examination of the lungs, palpation, percussion and auscultation reveal the findings of pneumonia In many instances the signs of cavitation appear at short intervals after the disease has begun Reports on examination of sputum are positive for large numbers of acid-fast bacilli which on culture and guinea pig inoculation prove to be tubercle bacilli

DIAGNOSIS The diagnosis is made by recovery of tubercle bacilli from the sputum The physical and the roentgenologic examinations reveal pneumonia.

In most cases of massive tuberculous pneumonia the prognosis is grave, as death usually ensues within a few weeks There is no specific treatment

3 ***Chronic Forms of Pulmonary Tuberculosis.*** In the chronic forms of tuberculosis the organisms may be either the human or the bovine type (rarely avian according to Feldman) Chronic ulcerative and progressive pulmonary tuberculosis is a reinfection type of the disease in adults and occasionally in children.

There is no good evidence that race and nationality predispose to the development of pulmonary tuberculosis The incidence of the disease in the Negro and the American Indian probably is due to poor sanitation which predisposes to contagion rather than reduced resistance The members of both races respond to tuberculosis control measures.

The development of pulmonary tuberculosis following whooping cough, measles, pneumonia, or pregnancy is probably coincidental to an environment full of the germs of tuberculosis The development of pulmonary or any form of tuberculosis in the diabetic patient is serious

Trauma does not cause tuberculosis The discovery of pulmonary tuberculosis in a recently injured individual is an accidental finding and has nothing to do with the injury

Chronic pulmonary tuberculosis frequently results from hematogenous spread of tubercle bacilli Insufficient numbers are released to cause a general miliary tuberculosis, consequently fewer bacilli are deposited in various places in the body, and the body is more able to cope with them The initial lesion, the tubercle, is a small lesion These smaller lesions extend into the air passages, particularly the smaller bronchial ramifications, after which sputum containing tubercle bacilli is expectorated, shadows on the roentgenograms appear, and other symptoms become evident

Chronic pulmonary tuberculosis may be produced by exogenous reinfections, by inhalation of tubercle bacilli, or by ingestion of the bacilli into the digestive tract,

from which they are taken up by the lacteals. They reach the blood stream and lodge in the lungs.

From either endogenous or exogenous reinfections bacilli may reach the larynx and pharynx by way of the trachea, may reach the digestive system through the esophagus, and may reach the urogenital organs, the nervous system and bones through the blood stream

Chronic pulmonary tuberculosis is most commonly situated in the upper lobes of the lungs but may appear anywhere in the lungs. There is a strong tendency for such lesions to undergo remissions and exacerbations, and at any time they may be permanently arrested or may continue to progress and cause damage beyond repair

SYMPTOMS A history of exposure to those who have open tuberculous lesions capable of discharging bacilli is obtained from less than one-half of the patients who have active pulmonary tuberculosis

The consensus is that the allergic reaction to the tuberculoprotein is responsible for the acute manifestations of tuberculosis. However, the greater part of the symptoms of pulmonary tuberculosis are due to a toxemia The toxemia is manifested by its effects on the sympathetic nervous system and endocrines, particularly adrenals and thyroid Pottenger enumerated the symptoms due to toxemias thus (1) malaise, (2) lack of endurance, (3) loss of strength, (4) nervous instability, (5) diminished digestive activity, (6) increased metabolic rate, (7) loss of weight, (8) increased pulse rate, (9) fever and (10) night sweats Any one, or any combination, of these symptoms may be present in tuberculosis. Every one of these symptoms may be present in a patient who does not have tuberculosis A patient may have advanced active tuberculosis and not have any of these symptoms

Malaise is so common a complaint in those who are well or sick that it has little or no diagnostic significance at any time If present, it is due to toxemia

A *lack of endurance* is not significant if it is detached from the past performance of the patient It is significant if the patient is unable to endure more than a small part of the day's work which has been performed in the past without exhaustion.

The *loss of strength* is a comparative estimation in regard to past performance without fatigue Patients may state that they are unable to do work, requiring the same strength, that they did easily in former years. In the young man or woman this may be significant In aging men and women who do not have pulmonary tuberculosis this is their most common complaint

Diminished digestive activity is often an early symptom in pulmonary tuberculosis It is accompanied by a loss of body weight. Pulmonary tuberculosis is one of the common causes of loss of weight. A loss of several pounds during a few weeks is always significant Indigestion often appears intermittently Digestive disturbances may be severe in one, and mild or even absent in another who has tuberculosis

The *pulse rate* in pulmonary tuberculosis, as in normal health, varies considerably Fever is attended by an increased pulse rate.

Fever is a significant symptom of early pulmonary tuberculosis. The presence of fever is determined by recording the temperature every 2 hours for a period of 4 or 5 days. Elevations of temperature do not always occur at the same time of day or night on successive days. The common opinion that the fever appears only during the afternoon is often correct If the temperature is taken by mouth, the thermometer should be held under the tongue for 10 and preferably 15 or 20 minutes To be of significance it must be 99 F (37.2 C) or more for men and 99.6 F (37.5 C) or more for women, and should not show wide variations from hour to hour. In those who have a wide range of fluctuation, the morning temperature may be as low as 97 F (36.1 C)

Temperature greater than 99 F may occur intermittently, for instance, elevated for a few days, then absent for a time. Three or 4 weeks of observation may be necessary in some instances to be certain fever is present. There is usually a slight elevation of temperature associated with the menstrual period or at the time of ovulation a week or two before the period. Slight elevations in temperature may occur after exercise

Night sweats are of frequent occurrence. These sweats occur after midnight while the patient is sleeping soundly.

Tuberculous patients may complain of *huskiness* or *hoarseness* of the voice without detectable changes in the larynx Huskiness of the voice occurs as a part of general weakness and may accompany any low-grade fevers from any cause.

Tuberculosis is one of the causes of *cough.* Acute and chronic respiratory infections, air contaminants, allergy, mitral stenosis and intrathoracic pressure are examples of some of the common causes of coughs Many tuberculous patients who have a cough attribute all the symptoms to it. They feel no pain or other sensation within the thorax but have an almost constant *tickling in the throat* This symptom is a reflex one. In early tuberculosis the cough may be nonproductive.

Thoracic pain is commonly present in those who have tuberculosis In the absence of pleural pain, which is manifested in association with inspiration, a person who has tuberculosis frequently complains of pains about the shoulders and in the thorax Pains of this distribution, however, are often complained of by those who do not have tuberculosis

The spitting of *blood-streaked sputum* may be the subject of complaint in tuberculosis as well as in many other conditions of the nose and throat Hemorrhages, varying in amount from 1 dram to the point of exsanguination and death, may occur. Death results from pulmonary hemorrhage in one third of tuberculous patients Contrary to former-day teaching that blood-streaked sputum often indicated pulmonary tuberculosis it is now known that hemorrhage from the lungs occurs much more frequently in nontuberculous conditions, such as bronchiectasis, than it does in pulmonary tuberculosis Patients are not fearful of small hemorrhages, for there are those who give histories of hemorrhage for months or a year or more before reporting for examination

A hemorrhage may be the first manifestation of a tuberculous lesion which

Sputum, if present in the early stages of tuberculosis, often is in small amounts, thin and clear, and resembling saliva As the disease advances, the sputum increases in amount, becomes thicker, and attains a yellow or green coloration

Frequent bad *colds* and *cough* which persist for weeks are manifestations of a failure in health There are many causes for such bad colds, but among these causes pulmonary tuberculosis is an important one

A preceding or a present attack of pleurisy is often the first clinical manifestation of tuberculosis

EXAMINATION On examination the patient often appears to be in good health, or there may be evidence of loss of body weight and flabbiness of the muscles. As the disease progresses, an extreme state of emaciation may develop. Often there is a detectable decrease in the expansion of the thoracic wall over the region of disease The excursion of the diaphragm is limited, hence the phrenic wave (Litten's sign) *is limited in range of excursion*

Often a patient who has pulmonary tuberculosis has a flushed condition of the cheeks The flushing may appear only at certain times of the day and is not synchronously present with fever The reddened cheeks may be unilateral or bilateral,

corresponding to the side of the lesion or lesions. The patient may complain of a hot sensation of the ear or the side of the face without the appearance of flushing. The burning and the flushing are due to dilatation of the blood vessels to the regions, produced reflexly by the stimuli passing upward over the vagus and peripherad over the fifth cranial nerve.

When the disease attains the moderately or far advanced stage, tactile fremitus is present. The percussion note is dull or flat over the involved portions. Auscultation reveals changes in breath sounds, varying from bronchovesicular to bronchial breathing. The whispered and spoken voice sounds are more audible over the tuberculous lesions than over the normal lung. Bronchophony may be elicited over sites of solidification, and pectoriloquy over the empty or partially filled cavities. Rales of the fine or moderately coarse variety are heard over the regions of disease which have reached the moderately or far advanced stage. Rales of a metallic or resonating quality are heard over cavities.

DIAGNOSIS OF PULMONARY TUBERCULOSIS. The following discussion is essentially an adaptation of material in *Diagnostic Standards and Classification of Tuberculosis* (1950), of the National Tuberculosis Association, and, in part, a quotation from that text. This material as adapted here is used by permission of the Association.

The diagnosis of tuberculosis includes a determination of the presence and situation of a tuberculous lesion and an evaluation of its pathologic characteristics; that is, whether the lesion is open or closed. Open lesions disseminate tubercle bacilli and therefore are dangerous or potentially dangerous to the patient and those with whom contact is made.

Because active open pulmonary tuberculosis often exists without symptoms or abnormal findings, both pulmonary tuberculosis with symptoms and pulmonary tuberculosis without symptoms are considered.

Pulmonary Tuberculosis Without Symptoms. The repeated roentgenologic examinations of apparently healthy contacts of known cases of tuberculosis disclose many asymptomatic but actually open and potentially dangerous lesions, particularly in adolescents. The mass roentgenologic examinations of apparently healthy groups in occupations or at ages in which tuberculosis mortality rates are relatively high have revealed lesions which may prove on further investigation and study to be minimal in extent but amenable to treatment.

Further study and observation of these minimal lesions consist of history, physical examination and serial roentgenologic examinations made at regular intervals of one to two months to determine the degree of instability of lesions. Sputum studies are made from time to time, temperature records are kept until it can be determined whether a lesion is active and in need of treatment. Reactors to tuberculin should be examined roentgenologically each six months to one year.

When applied to adolescents and adults, mass roentgenologic examination of the lungs has as its primary object the detection of active or potentially active tuberculosis. Mass tuberculin testing is commonly restricted to those of elementary school age or less, although in rural communities and other low-incidence areas it may be used to advantage among older age groups as a preliminary screening method.

Pulmonary Tuberculosis With Symptoms. Tuberculosis in its early stages seldom [illegible] atient to consult a physician. [illegible] there is constantly a history [illegible] chest pain, dyspnea, hoarseness, cough, and hemoptysis. The history of lassitude, loss of appetite, loss of weight, and slight elevation of temperature, and night sweats occurring in a young individual is particularly significant. A physical examination may reveal moist rales over a limited area of the upper third of one side of the chest. Occasionally the

abnormal signs are elicited over only a lower lobe. Such findings require a roentgenogram to be made of the chest; and, if there is sputum, it is examined for acid-fast bacilli. If negative on direct smear, specimens should be concentrated and, if necessary, culture or guinea pig inoculation is made If there is no sputum, gastric contents are obtained while the patient is fasting and are cultured or inoculated into guinea pigs The tuberculin test is given at the time of the first visit so that readings of the results may be made two or three days later. A negative reaction to a tuberculin test is strong evidence that the physical findings are not due to tuberculosis. A tuberculin reaction in itself should not be regarded as an indication of dangerous tuberculous infection, except in infants.

Obviously both the tuberculin test and the roentgenogram are of value in differential diagnosis of pulmonary disease. Occasionally repeated stereoscopic films and examinations in the lateral, oblique, and lordotic positions may be of definite value.

TUBERCULOUS COMPLICATIONS Three major complications of pulmonary tuberculosis are those in the larynx, the trachea and the bronchi. The larynx can be viewed readily. The trachea and bronchi require bronchoscopic examination, and sometimes even this will not lead to the diagnosis if the lesions are beyond the bronchoscopist's limited scope of vision. Tracheal or bronchial lesions may give no symptoms and yet produce positive sputum Lesions of the trachea rarely cause wheezing. The main clinical symptoms of bronchial disease are wheezing, severe coughing, and otherwise unexplained dyspnea, all of which are the direct result of reduction of the lumen of the bronchus Massive collapse of a segment of a lobe, of a lobe, or an entire lung sometimes results from this interference with aeration and drainage. The progress of this complication may seriously affect the management of a parenchymal pulmonary lesion

Involvement of the pleura is practically a constant finding in well-developed pulmonary tuberculosis Pleural effusions in young patients should be considered as of tuberculous origin unless proved otherwise A diagnostic tap for laboratory studies of the fluid is usually indicated Often at the time a patient complains of pain in the chest, immediate fluoroscopic or roentgenologic examination may not reveal evidence of effusion Repeating the examination after the pain has subsided will frequently result in the discovery of a pleural effusion

DIFFERENTIAL DIAGNOSIS OF PULMONARY TUBERCULOSIS The commoner conditions to be differentiated from pulmonary tuberculosis are the pneumonias, pulmonary abscess, low-grade bronchiolitis secondary to chronic sinusitis, bronchiectasis, neoplasms (especially bronchogenic carcinoma), various pulmonary fibroses (especially silicosis), sarcoidosis and fungous infections.

cavities and exudative lesions The symptoms are those of a prolonged influenza, and the diagnosis rests on the recovery of *Coccidioides immitis* from the sputum or pleural fluid Histoplasmosis is found chiefly in the Middle Western and Southeastern states, and it is not uncommon in these areas to see a number of small calcifications in roentgenograms of patients who have negative tuberculin and positive histoplasmin tests.

In sarcoidosis, patients often fail to react to the tuberculin test and have few if any symptoms in spite of roentgenograms showing hilar adenopathy and pulmonary lesions like those of far advanced tuberculosis, miliary tuberculosis or silicosis

Roentgenologic shadows are never pathognomonic, and when a person is in the age period in which cancer is most frequent, and specific evidence of tuberculosis or other disease has not been obtained, examination for malignant tumor should always be made.

SCREENING CLASSIFICATIONS USED IN MASS ROENTGENOLOGIC SURVEYS. During the years the public has become conscious of the ravages of tuberculosis and has done much through sanitary methods in the home and by demanding purer milk supplies to control this disease. Those in charge of mass roentgenography seem to think that this method has been successful in the finding of many who have pulmonary lesions requiring further study.

As the use of this technic increases, the need for uniform standards and classification of screening-film findings becomes apparent. The systematic terminology used by the National Tuberculosis Association which has proved to be practical and informative is presented here:

CLASSIFICATION OF PULMONARY TUBERCULOSIS *

Extent of Pulmonary Lesions. *Minimal.* Slight lesions without demonstrable excavation confined to a small part of one or both lungs. The total extent of the lesions, regardless of distribution, shall not exceed the equivalent of the volume of lung tissue which lies above the second chondrosternal junction and the spine of the fourth or body of the fifth thoracic vertebra on one side

Moderately Advanced. One or both lungs may be involved, but the total extent of the lesions shall not exceed the following limits.

Slight disseminated lesions which may extend through not more than the volume of one lung or the equivalent in both lungs.

Dense and confluent lesions which may extend through not more than the equivalent of one-third the volume of one lung.

Total diameter of cavities less than 4 cm

Far Advanced Lesions more extensive than moderately advanced

Extent of Pulmonary Lesions Following Therapy. In the case of temporary collapse, the extent of disease existing immediately before the collapse shall be continued in the classification until re-expansion permits reclassification

In the case of permanent collapse or pulmonary excision, the extent of disease in a lung existing immediately before excision or collapse shall be continued in this classification through life, except that such extension or new deposits of disease as appear any time postoperatively in this or the contralateral lung shall be additions to the preoperative classification. The form, site, and duration of the procedure shall be added in parenthesis to the classification of extent of disease.

In other cases the classification of extent will be changed as the change in the extent of the demonstrable lesion warrants Once the diagnosis of pulmonary tuberculosis has been established, however, the extent of the lesion cannot be classified as less than minimal even when clearing on the roentgenogram appears to be complete

Table 9-1. Bronchopulmonary Segments

RIGHT LUNG		LEFT LUNG	
LOBES	SEGMENTS	LOBES	SEGMENTS
Upper	Apical Posterior Anterior	Upper Upper Division	Apical Posterior Anterior
Middle	Lateral Medial	Lower (Lingular) Division	Superior Inferior
Lower	Superior Medial Basal Anterior Basal Lateral Basal Posterior Basal	Lower	Superior Anterior-medial Basal Lateral Basal Posterior Basal

* From *Diagnostic Standards and Classification of Tuberculosis,* 1950 Edition, with some re-arrangements of order of presentation

Location of Lesions. It may be useful to classify the extent of lesions in each lung separately. When this is done, however, the combined extent for both lungs should always be designated.

The location of lesions may be further designated by bronchopulmonary segments. The terminology and classification of Jackson and Huber * have been adopted upon the recommendation of the American Association for Thoracic Surgery.

CLINICAL CLASSIFICATION

The following definitions, subject to the interpretation of the physician, apply regardless of the type of treatment given Collapse therapy or pulmonary excision in effect at the time of classification will be indicated under extent of pulmonary lesions. The status of activity of lesions from a roentgenologic, symptomatic and laboratory standpoint is designated first, the status of a patient in terms of exercise shall be designated next.

Roentgenologic, Symptomatic, and Laboratory Status. *Inactive* Lesions as observed in serial roentgenograms must be stable except for extremely slow shrinkage, and there must be no roentgenologic evidence of cavity. Symptoms of tuberculous origin must be absent Sputum, if any, must be found negative for tubercle bacilli repeatedly, not only by concentration and microscopic examination, but also by culture or animal inoculation When a patient is not raising sputum or when there is any question concerning the authenticity or adequacy of expectorated sputum specimens, the fasting gastric contents or pulmonary secretions which have been aspirated from the tracheobronchial tree should be examined by culture or animal inoculation

These conditions shall have existed at least six months The period of inactivity shall be designated, if known, for example, Inactive (6 months), Inactive (2 years), et cetera.

Arrested. The symptomatic and roentgenologic requirements of this group are the same as for inactive, but the laboratory requirements are different.

When sputum specimens or gastric contents have been found negative by repeated microscopic examinations of concentrates but not by culture or animal inoculation, such patients cannot be classified as inactive but must be classified as arrested.

Patients may also be classified as arrested even though culture or animal inoculation may be positive and, among many concentrated specimens of sputum examined, an occasional positive is found microscopically

These conditions shall have existed at least three months The period of arrest shall be designated, if known, for example, Arrested (6 months), Arrested (2 years), et cetera

Active Lesions as observed in serial roentgenograms are usually progressive or retrogressive but may be stationary Symptoms of tuberculous origin are commonly present but may be absent Sputum and gastric contents almost always contain tubercle bacilli although, in some instances, tubercle bacilli cannot be demonstrated even after repeated cultures and animal inoculations With rare exceptions the tuberculin test is positive.

The period of activity shall be designated, if known, for example, Active (17 months), Active (3 years) The designations Active, Improved, or Active, Unimproved, may be used after an adequate period of observation or treatment.

Activity Undetermined When activity has not been determined from adequate roentgenologic and laboratory examinations, the disease must be designated temporarily as Activity Undetermined If a provisional estimate of the probable clinical status is necessary for public health purposes, the terms (a) Probably Active or (b) Probably Inactive should be used Every effort should be made to classify cases and to avoid this category

Exercise Status. The exercise status of a patient shall be designated:

I The patient is not ambulatory
II The patient has been ambulatory for less than one hour daily
III The patient has been ambulatory for one hour daily for a period of two months

* Jackson, C. L., and Huber, J. F. ... onchial Tree and ... Gray, Henry, in ... 1134-1135.

SCREENING CLASSIFICATIONS USED IN MASS ROENTGENOLOGIC SURVEYS. During the years the public has become conscious of the ravages of tuberculosis and has done much through sanitary methods in the home and by demanding purer milk supplies to control this disease. Those in charge of mass roentgenography seem to think that this method has been successful in the finding of many who have pulmonary lesions requiring further study.

As the use of this technic increases, the need for uniform standards and classification of screening-film findings becomes apparent The systematic terminology used by the National Tuberculosis Association which has proved to be practical and informative is presented here:

CLASSIFICATION OF PULMONARY TUBERCULOSIS *

Extent of Pulmonary Lesions. *Minimal.* Slight lesions without demonstrable excavation confined to a small part of one or both lungs The total extent of the lesions, regardless of distribution, shall not exceed the equivalent of the volume of lung tissue which lies above the second chondrosternal junction and the spine of the fourth or body of the fifth thoracic vertebra on one side

Moderately Advanced One or both lungs may be involved, but the total extent of the lesions shall not exceed the following limits·

Slight disseminated lesions which may extend through not more than the volume of one lung or the equivalent in both lungs.

Dense and confluent lesions which may extend through not more than the equivalent of one-third the volume of one lung

Total diameter of cavities less than 4 cm

Far Advanced. Lesions more extensive than moderately advanced.

Extent of Pulmonary Lesions Following Therapy. In the case of temporary collapse, the extent of disease existing immediately before the collapse shall be continued in the classification until re-expansion permits reclassification.

In the case of permanent collapse or pulmonary excision, the extent of disease in a lung existing immediately before excision or collapse shall be continued in this classification through life, except that such extension or new deposits of disease as appear any time postoperatively in this or the contralateral lung shall be additions to the preoperative classification. The form, site, and duration of the procedure shall be added in parenthesis to the classification of extent of disease

In other cases the classification of extent will be changed as the change in the extent of the demonstrable lesion warrants Once the diagnosis of pulmonary tuberculosis has been established, however, the extent of the lesion cannot be classified as less than minimal even when clearing on the roentgenogram appears to be complete

Lower	Superior Medial Basal Anterior Basal Lateral Basal Posterior Basal	Lower	Superior Anterior-medial Basal Lateral Basal Posterior Basal

* From *Diagnostic Standards and Classification of Tuberculosis,* 1950 Edition, with some re-arrangements of order of presentation

upon two factors: (1) the annual decrease of reactors to tuberculin among various age groups in the population; (2) the number of new cases and deaths reported annually that occur in families in which no tuberculosis has been known to exist previously. Careful observance of these two factors will give the best indication of the proper time for re-survey of any community or population group

DEMONSTRATION OF TUBERCLE BACILLI

The demonstration of virulent tubercle bacilli in the pulmonary secretions or gastric contents of patients with pulmonary disease is the one inescapable criterion of active pulmonary tuberculosis The results of other technical procedures, including roentgenologic examination, may be equivocal. However, if concentrated specimens from a patient are examined for tubercle bacilli by an expert at frequent intervals, the results, whether positive or negative, are of the greatest significance Since so much may depend upon a single sputum examination, certain precautions are necessary to make the examination as reliable as possible

Preparation of Glassware. All glassware used in sputum [collections and] studies must be scrupulously cleaned to ensure removal of any acid-fast matter which may adhere from previous use. Sputum bottles, after being autoclaved to ensure sterility, are held individually in a rapid stream of tap water to rinse out most of the organic matter The bottles are then boiled in soapy water for an hour, after which they are placed in cleaning solution for at least 12 hours to destroy any remaining organic matter. The cleaning solution is prepared by stirring 50 gm of technical-grade sodium dichromate into one liter of concentrated sulphuric acid (sp gr 1 82) After removal from this solution, the bottles are placed in a basin into which tap water is allowed to run rapidly for 30 minutes Finally each bottle is rinsed individually and dried and sterilized in an oven

Collection of Specimens. *Sputum* A wide-mouthed bottle of 30 to 300 ml capacity, cleaned as indicated above, should be used The bottle may have either a screw top or a snap cover The patient should be instructed to collect only secretion coming up the tracheobronchial tree from below the larynx, i e., not saliva or postnasal discharge. As used subsequently, the term sputum will refer only to secretion of this type coming from the lungs

Gastric Contents In certain cases, examination of the gastric contents for tubercle bacilli is essential. This is particularly true in children or other patients who do not raise sputum, as well as in patients whose sputum has failed to show tubercle bacilli after repeated examinations The technique of gastric lavage is as follows The material is collected after at least an 8-hour fast A Levine tube, carefully cleaned, sterilized, and lubricated with sterile water, is introduced through one nostril, the patient is asked to swallow as soon as he feels the tip of the tube in his throat With a glass syringe of 20 to 50 ml capacity, the gastric contents are withdrawn and placed in a sterile 250 ml. Erlenmeyer flask The patient is then given 30 to 50 ml of sterile water to drink, and the gastric contents are again aspirated and added to the first aspiration The specimen must be sent to the laboratory immediately and must receive the attention of the technician at once Prolonged standing may make the recovery of tubercle bacilli difficult or impossible Gastric specimens which must be sent through the mails may be frozen and shipped in dry ice It should be realized that, in the case of ambulant patients, a walk or long ride to the doctor's office may cause the stomach to empty before a gastric specimen is obtained

Other Clinical Specimens For the demonstration of tubercle bacilli in other body fluids, such as pleural, pericardial, or peritoneal effusions, spinal fluid, or pus from cold abscesses or sinuses, essentially the same methods are used as for sputum. . . .

To recover tubercle bacilli from urine, [at least] 1,000 ml taken from a well-mixed 24-hour specimen [is required]

Positive results from such voided specimens should be confirmed with catheterized specimens. These may be treated in the manner given above Also, it is advisable to inoculate the untreated sediment into guinea pigs.

In the examination of feces, [at least 5 gm. is required] . .

Negative Sputum. If sputums and gastric contents are carefully and repeatedly ve, negative results are of distinct diagnostic value. However, at a given specimen can never be called Negative for tubercle

IV. The patient has been ambulatory for at least two hours daily for a period of at least two months

V The patient is living under ordinary conditions of life.

The exercise status of a patient shall be designated following the designation of the roentgenologic, symptomatic and laboratory status; for example, Inactive (*6 months*) III.

Classification. Classifications of roentgenologic findings can be stated comparatively easily In summary, they may be listed as follows:

Screening Films of Any Size

1. Essentially *negative*
2. Unsatisfactory (technic)
3. Calcification only
4. Suggestive of tuberculosis
   a. Minimal
   b. Moderately advanced
   c. Far advanced

   Note *If* a provisional estimate is necessary, the terms probably active or probably inactive should be used for public health purposes
5. Suspected tuberculosis
6. Probably nontuberculous
   a Cardiac changes
   b Pleural changes
   c. Other changes
7. Diagnosis deferred

Explanation of Classification of Impression from Survey Films Following is a *brief* explanation of these classifications

1 Essentially negative. All apparently normal chests without evidence of present or past disease and without calcification

2. Unsatisfactory Technic unsatisfactory for screening, requiring retake

3 Calcification only (distinctly present in parenchyma or in hilum without infiltration)

4 Suggestive of tuberculosis Mottled, strand-like shadows especially in upper lobes, with or without evidence of cavity or associated calcification. The location and extent of abnormal shadows must be taken into consideration

a Minimal

b *Moderately advanced*

c *Far advanced*

5. Suspected tuberculosis Shadows of such character that opinion must be reserved until clinical studies can be made. This category includes such conditions as suspected hilar lymphadenitis, evidence of collapse therapy, and pleural effusion.

6 Probably nontuberculous. a Cardiac changes Abnormalities of size, shape or position of heart or aorta

b. Pleural changes Localized or extensive pleural thickening in the absence of other evidence of tuberculosis.

c. Other changes, such as tumors, silicosis, other pneumoconioses, or pneumonia

7. Diagnosis deferred Abnormal shadows not classifiable in the categories described above

Films regarded as suggestive of tuberculosis should be further qualified as (1) probably active or (2) probably inactive However, the diagnosis of tuberculosis and the estimate of clinical status of such cases should be provisional for all initial or screening examinations, even if the initial survey film is a 14 x 17 inch celluloid film

It should be emphasized that final diagnosis should *never* be made from survey roentgenograms alone, regardless of the technic employed One can be certain of exact diagnosis only after meticulous laboratory and clinical studies. Such studies should include clinical history, a physical examination, sputum examinations, gastric or tracheal cultures when necessary, tuberculin testing and serial roentgenologic examination The above classification, therefore, is for screening purposes only

Intervals for Re-Surveys. No arbitrary time interval can be recommended for re-survey of large population groups. The completeness of the initial survey, adequacy of isolation and treatment of newly-discovered infectious persons, and *follow-up* examinations of contacts of known cases will determine the need for or frequency of re-survey. Epidemiologically, the real test of the time interval of re-surveys will be based

of tuberculosis are, in the vast majority of instances, highly sensitive to PPD or Old Tuberculin. A dose of 0 00002 mg. of PPD or 0 01 mg. of Old Tuberculin is recommended for the initial dose for those living in areas having a high morbidity or mortality from tuberculosis, for those with a history of severe reactions following previous administration of tuberculin, for those with a history of intimate contact with persons with clinically manifest tuberculosis, and for persons with extrapulmonary forms of this disease.

If PPD is used, a standard product, which is available on the market, is dissolved in the requisite amount of the diluent supplied so that each 0 1 ml. of the dilution will contain 0.0001 mg of PPD To prepare the dose of 0 1 mg. of Old Tuberculin recommended for case-finding purposes, 0.1 ml of concentrated Old Tuberculin is added to 9 9 ml. of sterile physiological salt solution, thus making a dilution of 1:100. One milliliter of the 1:100 dilution of Old Tuberculin is transferred to 9 0 ml. of sterile physiological salt solution, thus making a dilution of 1.1,000 Each 0 1 ml of this dilution will contain 0 1 mg of Old Tuberculin Purified Protein Derivative and the diluted Old Tuberculin are best prepared fresh. Solutions more than a few days old should not be used When not in use, diluted solutions should be kept in a refrigerator.

For the present, with certain exceptions as noted, the use of a single dose is recommended Further studies on the specificity of the larger doses of both PPD and Old Tuberculin are being made

The intracutaneous tuberculin test (Mantoux) with either PPD or Old Tuberculin should be read 48 or 72 hours after the injection Readings should be made in a good light with the arm slightly flexed Response to injection is classified as positive, negative, or doubtful. Reactions may be classified arbitrarily as one, two, three or four plus depending upon the extent of induration measured at its widest diameter. A reaction showing some definite induration more than 5 mm and not exceeding 10 mm. in diameter is recorded as a one plus (+) reaction A two plus (++) reaction is an area of induration measuring from 10 to 20 mm in diameter. A three plus (+++) reaction is characterized by marked redness and induration exceeding 20 mm. in diameter A four plus (++++) reaction consists of severe induration and an area of necrosis. A reaction with a trace of induration measuring 5 mm. or less in diameter is rated as doubtful Redness without associated induration does not constitute a reaction.

Syringes which have been used for the administration of PPD or Old Tuberculin should not be used for the administration of preparations such as coccidioidin, histoplasmin or other diagnostic reagents since PPD and Old Tuberculin are difficult to remove from the syringes

Scarification or Pirquet Test This procedure is carried out by applying a drop of undiluted Old Tuberculin to the cleansed skin, preferably over the region of the deltoid muscle, and scarifying the skin through the drop of tuberculin by means of a sterile needle or small borer Care should be taken that the scarification does not cause bleeding. The tuberculin should be permitted to remain in situ for about 20 to 30 minutes before the excess is removed The results of the test are read 48 to 72 hours later and are interpreted in the same manner as the intracutaneous test. If there is no tuberculin reaction by this method, it is advised that it be followed by the administration of 0 0001 mg of PPD or 0 1 mg of Old Tuberculin, using the intracutaneous method.

Patch or Percutaneous Test of Vollmer The patch test is carried out by applying a prepared patch to the skin in the region of the sternum or between the scapulae. The patch is composed of two squares impregnated with concentrated tuberculin prepared from cultures grown on a synthetic medium and one control square impregnated with [illegible] n is first cleansed with acetone and the patch [illegible] 48 hours The reaction is read 48 hours after [illegible] ears as an inflamed area of varying intensity. In those highly sensitive to tuberculin, it is advisable to remove the patch as soon as the person complains of irritation since a severe local reaction with blistering may occur. If the patch test is negative, 0 0001 mg of PPD or 0.1 mg of Old Tuberculin should be injected

Of the procedures here described, the intracutaneous method is the most sensitive and permits the administration of graduated and accurate amounts, thus making it

bacilli until it has been examined by adequate cultural methods and animal inoculation as well as by examination of the direct and concentrated smears In a patient with a demonstrable parenchymal infiltration, in whom tubercle bacilli cannot be demonstrated, causes for the lesion other than active pulmonary tuberculosis should be sought.

In a tuberculous patient no specified number of negative sputum examinations gives absolute assurance that another specimen may not show tubercle bacilli. Nevertheless, it is convenient to designate an arbitrary number of negative examinations which may be taken as presumptive evidence of bacteriologic remission. To designate sputum as negative in this limited sense, it is recommended that three adequate specimens of sputum or of gastric contents, taken at least a week apart, be found negative by culture or by animal inoculation

TECHNICAL PROCEDURES

The Tuberculin Test. The tuberculin reaction is an acute, local, specific inflammation resulting from the injection or application of tuberculin. Few procedures employed in the control of tuberculosis are of greater value than the tuberculin test As an index of the extent of infection in communities, it is of the utmost epidemiological value It locates sources of contagion and provides a guide for case finding and family and group supervision. Its importance in the diagnosis of tuberculosis rises constantly as the rate of infection in the population decreases and as the total number of cases of active disease declines Whereas its value in clinical diagnosis once was exclusive rather than definitive in character, the tuberculin test is becoming a more positive indication of significant infection Finally, with the expansion of BCG vaccination programs and the importance of determining the relation of artificial infection with an organism of low virulence to the development of individual resistance, the tuberculin test has become of special significance as an indication of the take of the vaccine

Obviously, once BCG has been administered, the tuberculin test loses its specific value as an indicator of natural infection

A reaction to certain specified amounts of tuberculin is an indication of tuberculous infection With few exceptions, definite sensitivity to tuberculin once acquired persists through life This sensitivity may vary in intensity and may temporarily decrease or disappear in the course of high fever, exanthematous disease, miliary tuberculosis, and the last stages of pulmonary tuberculosis A very small percentage of persons may fail to react to tuberculin even after infection resulting from exposure to cases of open tuberculosis or after the administration of vaccine prepared from living or dead tubercle bacilli. The tuberculin test remains negative in a high percentage of cases of sarcoidosis

At the present time Purified Protein Derivative (PPD) and Old Tuberculin (OT) are widely used Purified Protein Derivative (PPD) is the tuberculin of choice and is recommended as the standard for comparative studies. It is prepared by growing tubercle bacilli on a synthetic medium of known composition. The tuberculin protein produced in the medium is then obtained by precipitation with ammonium sulfate at neutrality and further purification. Old Tuberculin is prepared by concentrating by heat the glycerine broth medium upon which the tubercle bacillus has grown

TECHNIC The method of choice in administering tuberculin and the one recommended for accuracy and for all general purposes is the intracutaneous (Mantoux) test Occasionally, however, special circumstances may make other methods of administration preferable. In the following paragraphs the intracutaneous method is described as the standard procedure A description is also given, however, of the scarification (Pirquet) test and of the Vollmer patch test, which is frequently employed when there is objection to the use of a needle Neither of these tests is considered as accurate as the intracutaneous test, in which a measured amount of tuberculin is introduced into the skin

Intracutaneous or Mantoux Test The intracutaneous tuberculin test is best carried out by injecting the desired concentration of PPD or Old Tuberculin into the cleansed skin of the forearm. This injection is made with a short (half inch), sharply beveled 24- or 25-gauge platinum or steel needle and a tuberculin syringe. When the injection [illegible] immediately at the site of injection

[illegible] or 0.1

[illegible] recom-

[illegible] teristic

mended since [illegible]

diagnosis of such diseases must depend on laboratory studies of materials obtained from patients, including direct microscopic examination of sputum, cultures of sputum, pathogenicity tests of organisms isolated, and sensitivity and serologic tests. *Actinomyces bovis, Nocardia asteroides, Candida albicans, Geotrichum candidum* and *Histoplasma capsulatum* are best detected in stained smears of the sputum (see Chapter 17).

India ink preparations are used to demonstrate the capsule which surrounds the budding, yeastlike cells of *Cryptococcus neoformans.* A medium containing penicillin and streptomycin supports the growth of pathogenic fungi with two exceptions, *Actinomyces bovis* and *Nocardia asteroides,* which are susceptible to penicillin and streptomycin and must be cultivated on other mediums Most fungi known to cause pulmonary infections are pathogenic for one or more laboratory animals such as mice, rabbits and guinea pigs Many patients with fungous infections manifest sensitivity to the invading organism or its products, and intradermal injec- [illegible]

[illegible]

positive serologic reaction in coccidioidomycosis, histoplasmosis and blastomycosis, in which the complement fixation tests have been used most extensively, is indicative of an active, progressive disseminated infection Such a test is therefore diagnostic. Cross reactions are known to occur between *Blastomyces* antigens and antiserum against *Histoplasma capsulatum.* Any serum tested should be tested against both *Blastomyces* and *Histoplasma* antigens

TUBERCULIN, COCCIDIOIDIN AND HISTOPLASMIN SENSITIVITY IN RELATION TO PULMONARY CALCIFICATIONS In view of the evidence that histoplasmosis and coccidioidomycosis may be etiologically associated with pulmonary calcification, Beadenkopf and associates included these antigens among the skin tests given as part of the tuberculosis control program at the University of Chicago Only 30 per cent of the students enrolled came from Chicago and vicinity, the greater number came from practically all parts of the United States, and several hundred were from foreign countries The report was based on the study of 6,000 students registered at the University from January 1 to October, 1947 This study on a population of diverse origin confirms the results of other recent surveys. It was found that (1) the prevalence of tuberculin sensitivity progressively increased from 10 per cent among the youngest age group to 57 per cent among those 50 years of age; (2) the rate of histoplasmin sensitivity began at 10 per cent among the youngest group and reached 38 per cent in the oldest group, (3) pulmonary calcifications were associated with histoplasmin sensitivity twice as frequently as they were with tuberculin sensitivity, and (4) the prevalence of both histoplasmin sensitivity and pulmonary calcifications [illegible]

[illegible]

by tuberculin cutaneous testing In this area from one third to four fifths of young persons have pulmonary calcification Only one half or less of those who have pulmonary calcification have positive tuberculin reactions.

Anergy or loss of sensitivity to tuberculin from complete healing of the tuberculous process may be an acceptable explanation in some instances but this cannot explain the decided prevalence of pulmonary calcification in this area.

Cox and Smith, Aronson, Saylor and Parr and others have shown that in certain areas of the West coccidioidomycosis is responsible for a primary complex which goes on to calcification. The suggestion of Smith that histoplasmosis occurs most frequently in the area where pulmonary calcification is high in those whose reaction to tuberculin is negative seemed to offer a good working hypothesis

possible to detect cases with a low threshold of sensitivity to tuberculin. The general use of the Pirquet and the patch test is not recommended since they are not so efficient as the Mantoux test

Methods of Case Finding in Tuberculosis. The facilities used in case finding have continually been improved. At first the only means of finding tuberculosis was by physical examination; then came the discovery of the bacilli and the use of the microscope, and then the roentgen rays Following this the tuberculin test was applied with much success, and finally the miniature roentgenogram was developed

The mass roentgenologic survey method in large communities is probably most effective and cheapest, this is true especially of the 70 mm. machine, which may be used with all the facility of the earlier developed 35 mm., and yet possesses most of the advantages of the larger (14 by 17 inch) films The cost is not large, and the results are probably of more direct value than those obtained with any other method. The roentgenologic method finds the significant lesions which can be quickly treated.

Several things roentgenologic surveys do not do. Since roentgen shadows are not specific they are not pathognomonic of tuberculosis. Subsequent sputum analyses and tuberculin tests are necessary in 3 to 5 per cent of all cases surveyed, often revealing that conditions which at first were called tuberculosis actually are some other disease Second, the roentgen rays will not always reveal the presence of tuberculous lesions, since about 30 per cent of the chest area is hidden, and since many early lesions do not cast shadows.

The tuberculin test method, as introduced by Opie, Long, Meyers and a large number of others, has many advantages not possessed by any other technic. A tuberculin test helps to rule out nontuberculous disease. When the reaction is positive in infants and young children and even in young adults, the test is a certain indication of proximity to open tuberculosis. Because more persons will reach adult life in the future without infection, the test will become increasingly useful

One of the greatest benefits of tuberculin testing in survey work is found in communities where only 30 per cent or less of the population has a positive tuberculin reaction Obviously the majority of the roentgenograms of those with negative tuberculin reactions would be wasted The tuberculin method in such circumstances should be used first and followed by roentgenograms of the positive reactors Finally, when used fully, the tuberculin test is perhaps the best index of the efficiency of a tuberculosis control program in any community.

The tuberculin survey method is the most practical in communities where the infection rate is low Positive reactors may be given roentgen examinations after a tuberculin survey on entering and on leaving school. Follow-up of all contacts should be made and health education intensified.

In larger communities where the infection rate is high, probably the best method is to give roentgen examinations to everybody more than 15 years of age and the tuberculin test to all those with suspected lesions. Although a few small lesions will escape the roentgenologic survey, the number will not be of great importance The cost of each method when used in its respective proper setting is probably about the same, based on the total cases surveyed The roentgenogram is cheaper per number of cases found and number of deaths from tuberculosis, while the tuberculin test method is more useful in small communities and is, above all, a sound index of the control of the disease These two principal methods should and do supplement each other, the choice and sequence depending on time, place and available facilities.

Differentiation of the Active Phases of Pulmonary Mycosis and Tuberculosis. *Actinomyces bovis, Nocardia asteroides, Coccidioides immitis, Blastomyces dermatitidis, Blastomyces brasiliensis, Histoplasma capsulatum, Cryptococcus neoformans, Candida albicans* and *Geotrichum candidum* cause subacute and chronic infections of the lungs which resemble tuberculosis These diseases often cannot be separated and never can be definitely diagnosed on clinical findings alone The incidence of these mycotic infections is as a rule low in comparison with the incidence of tuberculosis. In the absence of positive smears, cultures and guinea pig inoculations for tuberculosis these mycotic diseases should be considered The

it is certain that no outside contact has been made within a year, there has never been during the residence of foreign observers in these communities the slightest evidence of acute infections of the respiratory tract Let there be contact with outsiders, and these communities will have an epidemic of colds within 2 days. It must be emphasized, however, that despite the studies which have been made in these communities, in reality the number of studies has been small and the time spent in these localities by investigators has been for practical purposes too short to establish the conclusions which have been reached.

From the data now obtainable it seems likely that a virus is present in the nasal discharge of patients during the first 3 or 4 days of an attack of a viral cold. This virus, when dispersed in the air or on objects in the open air, remains infective for about 5 hours The virus is said, too, to be spread by contaminated hands, either directly or indirectly. Likewise drinking glasses, cups, forks and spoons are excellent vehicles for the transmission of the cold virus, as well as other germs, from one person to another However, it has not been proved that colds are thus epidemically disseminated

INCIDENCE. Colds are more prevalent during the winter months than in other seasons in both *cold and temperate climates.* They seem to go around several times during the winter months of each year.

The prevalence of colds is about the same in the agreeable climates and the disagreeable climates Sleeping on sleeping porches, in well-ventilated bedrooms, or in poorly ventilated bedrooms does not affect individual susceptibility

During the winter months of each year there is a tendency for colds to increase when there is a decrease in temperature below the normal range of temperature for the corresponding week and also for the preceding week.

ETIOLOGY Among the various etiologic agents which deserve mention are viruses, bacteria, chilling, physical agents, allergies and climate.

Viruses. Dochez and his associates concluded that colds can be transmitted from man to the chimpanzee and from man to man by means of Berkefeld filtrates of nasal washings from individuals suffering from acute colds, and that the cause of colds is "a filtrable agent which in all likelihood belongs to the group of so-called submicroscopic viruses " The conclusion seems justified that a filtrable virus is the cause of certain colds and probably of some epidemics but not all of them.

Bacteria Colds of bacterial origin begin with a severe sore throat with the nasal discharge and congestion appearing later as the infection extends upward into the nasal passages. It seems that bacterial colds may appear in the course of a viral cold, and are probably due to secondary bacterial invaders. The vasomotor reaction may so disturb the equilibrium between the host and the bacteria of the nose as to favor the development of infection

Allergies The symptoms which allergens produce in the upper portion of the respiratory tract are essentially those of an acute coryza However, there seem to be regularly, each year, the so-called spring and fall colds in addition to these allergic phenomena

Physical Agents These include climates, good or bad, chilling of the body, and injury of the mucous membranes by particulate matter.

The exposure of an individual to drafts and *chilling of the whole or of portions of the body* may result in the symptoms of a cold It has been demonstrated that chilling of the body surfaces leads to peripheral vasoconstriction with attendant peripheral stasis and anoxemia, to lowered leukocyte response, and to impairment of the phagocytic capabilities of the fixed tissue cells, including those of the nasal mucous membrane Chilling of the body surfaces causes a fall in the temperature of the nasal and pharyngeal mucous membranes, and this chilling and the accompanying congestion increase susceptibility to a cold

The occurrence of colds in different geographic locations has illustrated that the attack rates are uniform, irrespective of latitude, longitude, or climate. The period of high incidence and the occurrence of epidemics in widely different localities often take

Christie and Peterson accordingly began to perform cutaneous tests with extracts of *Histoplasma capsulatum* and to look for nonfatal examples of the infection. The fungus *Histoplasma capsulatum* had been reported to cause acute and subacute granulomatous lesions progressing with great regularity to a fatal termination Their studies enabled them to observe examples of a benign form of histoplasmosis and to discover that many people react to extracts of the fungus.

The studies of Christie and Peterson and of Palmer and Furcolow show a remarkable relationship between sensitivity to histoplasmin and the development of pulmonary calcification. The early development of sensitivity to histoplasmin, followed by the development of the calcification at a rate much greater than the age specific rate of sensitivity to tuberculin, suggests that most of the lesions are more likely to be related to the development of sensitivity to histoplasmin than to be associated with tuberculosis.

According to Aronson and his co-workers, Indians of the United States and Alaska who failed to react to the intracutaneous injection of 0.00002 and 0.005 mg of Purified Protein Derivative of tuberculin revealed calcified pulmonary nodules Among 704 children living on the Pima Agency who did not react to tuberculin, calcified pulmonary nodules were observed in 102; among 419 on the Wind River Agency only 1 of those who failed to react to tuberculin had a calcified pulmonary nodule, among 332 children living on the Turtle Mountain Agency who did not react to tuberculin, 15 had calcified pulmonary nodules, and among the 592 children of the Rosebud Agency and the 977 children living in southeastern Alaska who failed to react to tuberculin 6 and 2 presented calcified pulmonary nodules Because of the high incidence of calcified pulmonary nodules in tuberculin negative children living on the Pima Agency the possibility that the nodules were coccidioidal was investigated A large percentage of children of school age living on the Pima, San Carlos and Sells agencies and a small percentage of those living on the Fort Apache Agency reacted to the injection of 0.1 ml of a 1:1,000 dilution of coccidioidin.

DISEASES OF THE RESPIRATORY PASSAGES AND THE LUNGS DUE TO FILTRABLE VIRUSES

The Common Cold. The consensus is that the common cold and its complications in the United States are the cause of more illness and disability than any other illness It must be clear that the term cold is applied by the physician and laity alike to various acute, subacute, and even chronic maladies of both the upper and lower portions of the respiratory tract, and thus statistical data concerning the incidence and the duration of the common cold are well-nigh impossible to interpret The term coryza refers to a cold in the head.

An acute respiratory infection often does not remain limited to any one portion of the respiratory tract For instance, rhinitis today may become sinusitis, pharyngitis, laryngitis, tracheitis or bronchitis tomorrow. In many instances the sequence may be changed, partially at least Tracheitis, laryngitis or pharyngitis may be largely over in a day or two, to be followed by rhinitis In reality, many individuals regularly with each cold have symptoms which commence as pharyngitis, laryngitis or tracheitis, to be followed by coryza.

EPIDEMIOLOGY. Colds are cosmopolitan in distribution in regard to geography, altitude and age incidence The attack rate is highest and the complications are most frequent and most serious in infants and in the aged. From these ages the rate declines to a low point in the age group 15 to 24 years, rises from 25 to 34 years, again declines until it reaches a minimum in the age group of 50 to 60 or 65 years and then tends to increase.

ISOLATION Some extraordinarily interesting observations on the occurrence of colds have been made in isolated communities. In the arctic and polar regions, when

respiratory tract such as laryngitis, tracheitis, bronchitis and pneumonia. Closely allied to colds are the diseases influenza and tonsillitis

It is postulated that complications of the common cold may occur when drainage from the sinuses or middle ear is obstructed by swelling of the mucous membranes. The presence of virulent organisms in the nose and throat at the time of the cold is likely to originate disease when the subject is in poor health.

DIAGNOSIS. The diagnosis of a common cold is a presumptive one until the patient has fully recovered The diagnosis of a complication of a bad cold depends on the excessive localization of symptoms and signs to the sinuses, ears or lungs. It is well to recall that some of the aches in the back, muscles and head are due to fever. Anorexia is due to loss of the senses of smell and taste Constipation is occasioned by lack of food In some instances diarrhea may be due to cold remedies which have been self-administered

Influenza. Influenza is known also as grippe, grip, febrile catarrh, catarrhal fever, acute nasopharyngitis, epidemic catarrh and epidemic influenza.

Influenza is an acute, self-limited, infectious disease of man which is caused by a virus of the influenza group. The illness is characterized by symptoms which are predominantly constitutional, although the infection is limited to the respiratory tract. It tends to occur in epidemic forms Two specific and distinct etiologic types of the disease are now recognized one, termed influenza A, is caused by infection with influenza A virus, the other, termed influenza B, is caused by infection with influenza B virus (Horsfall, 1940) The cause of pandemics of influenza has not been established

Among the periodic outbreaks of influenza the major ones are apparently due chiefly to influenza A virus, others may be due wholly or partly to influenza B virus; still other viruses may produce morbidity but may fail to show signs of their presence, although the illnesses produced by these as yet unproved viruses are clinically like those of known influenza A and B viruses Influenza A virus varies from one outbreak to another, antigenically, and in its rapidity of spread in the population. Influenza B virus produces epidemics of limited scope Influenza A virus usually lies quiescent for 21 months out of 24 During this quiescent interval there is some relationship between the individual immunity and the level of neutralizing antibodies in the serum

Influenza viruses may vary greatly from one epidemic to another. As an example of the variability of the influenza virus, according to Tamm, Kilbourne and Horsfall the influenza B virus isolated in the New York area during the 1950 epidemic was so different from previous strains as to throw doubt on the desirability of continuing the use of a routine strain exclusively in prophylactic immunization Using the chick embryo technic, four strains of influenza B virus were isolated from hospitalized patients Tamm, Kilbourne and Horsfall had for comparison the routine virus and five strains isolated by the same technic during previous epidemics (1945, 1947, 1949). Thus it is possible that it will be necessary to use a polyvalent influenza B vaccine in the future rather than to depend on the Lee strain exclusively.

Influenza viruses are not known to be related to the etiology of the common cold

EPIDEMIOLOGY The consensus is that a primary epidemic occurring in any locality after a period of years nearly free from the disease, is a uniform disease Influ [illegible]

[illegible]

decr [illegible]

The fatality rate, although variable, is low.

Primary epidemics are followed by secondary epidemics which are less extensive and more slowly reach their maximum, from which they decline more slowly and irregularly. Because of secondary pulmonary complications, the fatality rate is greater in the secondary epidemics than in the primary epidemic.

Influenza regularly occurs in endemic or seasonal form in most countries every

place synchronously, too fast for human travel and thus transport of the offending etiologic agent.

Temporary irritation or injury of the membranes of the nose and throat by *particulate matter* such as various dusts will cause the nasal symptoms characteristic of colds If the exposure to irritation is prolonged, the symptoms may subside or may become chronic and severe Smoking of cigarettes may be a factor in keeping up a low-grade *chronic irritation* Irritating chemical gases or air filled with particulate matter (dusts) or overheated dry air predisposes to colds

Indeterminate differences in individual susceptibility to colds cannot be explained

Some individuals seem to have hypersusceptibility to the common cold. Others are rarely susceptible to colds under any circumstances. These variations cannot be adequately explained by hypersensitivity due to an allergic state, or by immunity.

In persons who have frequent colds the vasomotor response of the nasal mucous membranes to peripheral cold stimuli is much less in degree and slower in appearance than in normal persons, and during an acute cold this reaction is entirely absent

Persons who are taking active physical exercise and who have accustomed themselves to rapid changes in temperature are less susceptible to colds than other persons even if they have the foredescribed mucous membrane attributes.

SYMPTOMS. The common cold commences in one or more of several ways. Often the first symptom is a feeling of congestion in the nose with sneezing Other colds will begin first with a general ache and perhaps slight fever, the temperature from 99 to 100 F (37 2 to 37 7 C), and still other colds will be accompanied with general aching, malaise, and loss of appetite for a day or more before there are any respiratory symptoms. Once any one or all of these discomforts are established, symptoms in the nose and throat ensue There is localized or generalized burning in the nose and throat. The discomforts spread and the mucous membranes of the nose, nasal sinuses and pharynx become red and swollen As the result of swelling of its mucous membranes, the nose becomes obstructed so that mouth breathing is more comfortable than nose breathing If the sinuses are prevented from draining by the swelling, there is a dull ache in the face and head The inflamed mucosa secretes a watery, serous exudate which drips almost constantly from the nose. This watery secretion is irritating to the outside skin of the nose and the upper lip.

The inspiration of cold air, dust or tobacco smoke hurts the nasal passages. Often confirmed cigarette and cigar smokers cannot tolerate their favorite pastime because the smoke hurts the nose and throat and may make the headache worse Involvement of the eustachian tubes causes noises created by the mucus and air in the tubes to be heard as popping and roaring sounds in the ears. If the eustachian tubes become closed, temporary deafness follows. The throat becomes dry, swollen and uncomfortable The tongue is dry. The senses of taste and of smell are impaired or lost A decrease in the degree of the acuity or a permanent loss of either or both the senses of smell and taste may follow a cold. However, recovery of the senses (hearing, smell and taste) is almost invariably the rule.

Slight fever may accompany acute colds A moderate or a high fever, the temperature more than 102 F (38 8 C), indicates more than a cold, for instance, some complication such as sinusitis, otitis media, tonsillitis, bronchitis or pneumonia

Involvement of the lower part of the respiratory tract with hoarseness and coughing is commonly present in some individuals; in others it rarely occurs.

EXAMINATION. Examination by physical means reveals the linings of the nose, the pharynx and throat to be reddened. The voice often is husky or lost Nasal or labial herpes may be found. If the mucous membranes of the tear ducts are swollen, the eyes are watery and the conjunctivae are injected. The lungs are clear.

An important reason for a complete physical examination of the patient who has a bad cold is to search for evidence of complications The complications of colds are sinusitis, otitis media, and more than transient infections of various parts of the

pneumonia of influenza is generally combined with capillary bronchitis upon which it supervenes. The instances in which pneumonia is combined with bronchitis are less commonly fatal than those in which capillary bronchitis alone existed.

Gastrointestinal Form This form of influenza begins with severe colicky pains, vomiting, and diarrhea. In this form, and in the nervous form, the catarrhal symptoms are often altogether absent, or only come on late in the course of illness.

Nervous Form The nervous form is characterized by intense headaches and backache. The backache may be as severe as that which occurs during a hemolytic crisis or in smallpox The headache, frontal, in some cases occipital, and occasionally vertical, is often persistent, continuing for some days after the patient's temperature has subsided to normal values.

The nervous form of influenza occurring in tropical and subtropical regions may be difficult to differentiate from dengue (six day fever, breakbone fever) except by laboratory tests.

SYMPTOMS. The onset of influenza is sudden On this point all of those who have reported the epidemics which have occurred from remote to recent times have agreed

Fever is constantly present except in cases in which pronounced nervous symptoms exist. The temperature may reach high figures, 105.8 F (41 C) early in the course of the disease, but if defervescence is rapid no great harm is done. The fever lasts from 3 to 10 days; the longer the fever continues, the more likely it is to resolve by lysis.

Coryza or *rhinitis*, or both, vary greatly in different epidemics of influenza. In most instances there is some degree of involvement of the respiratory system. In the total number of persons who have the disease these symptoms are not severe. The respiratory rate is usually not increased unless there are pulmonary complications. An early increase in the respiratory rate is an ill omen

Cough is not always a prominent feature, and often it is absent. The cough bears but little relation to the extent of the physical signs in the lungs. It is likely to occur in paroxysms which are sometimes very exhausting Toward the end of the grave illnesses cough, which may have been very troublesome indeed in the earlier stages, generally ceases, even though the lungs are full of rhonchi and rales

Pain may be the earliest symptom of influenza. Pains in the limbs and back, shivering, and often severe headache may be the only symptoms for a day and a night. The pains are referred almost invariably to the muscles and soft tissues, and to a less extent to the joints rather than to the bones themselves The commonest sites of pain are in the muscles of the thighs and calves, the lumbar muscles and muscles of the back of the neck, and to a less extent the knees and ankle joints. The pains are severe but differ considerably from those of trench fever and smallpox In these diseases the pains are most frequently referred to the bones themselves, particularly to the inner and outer edge of the tibiae, and the bones are often very tender to palpation The acute nocturnal exacerbations of the pains are more marked in trench fever than in influenza

The abdominal pains in some of those who have influenza are more general, and [illegible]

not tend to become localized, and the fever and pulse rate do not indicate a progressive lesion

There are those who have occipital headache and pain in the neck closely resembl [illegible]
is muc [illegible]
sign is [illegible]
a true Kernig's sign Lumbar puncture may, however, be necessary to exclude cere-

year. The exact relationship of endemic influenza to the classic pandemic type of influenza is unknown. Many believe that endemic influenza and the minor outbreaks are a repetition of the classic type, but during a period of attenuation of the virulence of the virus; others suggest that endemic or sporadic influenza is an infection of a different nature or type altogether.

The frequency of the outbreaks of influenza and its tendency to reach pandemic proportions, affecting equally those of all economic and social levels of society, traveling from continent to continent at a speed equal to that of human travel, affecting and destroying millions of lives (the 1918-1919 pandemic with 21,642,283 deaths), respecting no barriers set up for control by public health organizations, and leaving behind ill health and disease, stigmatize influenza as the greatest pestilence of our time The importance of this disease, in addition to its own morbidity, lies in its power to induce a condition of particular susceptibility to attack by secondary pathogenic organisms, particularly the hemolytic streptococcus and tubercle bacilli

The pneumonia which often follows influenzal infections is caused by an associated bacterial invasion of the lungs In cases of *Staphylococcus aureus* pneumonia complicating sporadic instances of influenza, the staphylococcus is present in almost pure culture. The hemolytic streptococcus (type A) is more commonly present in the various epidemics of pneumonia following influenza. The pneumococci and *Hemophilus influenzae* may be the bacterial agents responsible for some of the pulmonary complications It seems reasonable that the influenza virus itself may be capable of originating bronchopulmonary reaction if not an actual pneumonia The diffuse bronchiolitis which may occur after epidemic influenza may represent a true viral lesion of the lung.

The effect of endemic influenza on the morbidity as well as on the mortality rate from pneumonia and tuberculosis, and on the birth rate is less marked than that of the pandemic disease Prevalence of endemic influenza is more influenced by seasonal conditions as compared with the pandemic type

PATHOLOGY. The evidence would indicate that the filter-passing virus of influenza gains access to the body by the respiratory tract. The influenza virus injures or *destroys the ciliated epithelium lining the air passages.* It inflicts an initial damage of the epithelium of the respiratory tract at special selective sites In this respect stress is laid on the importance of the postnasal area as an important pr[illegible] infection in the body From this area the virus may [illegible] severe damage in the ciliated epithelium in the lowe[illegible] importance is laid on the very frequent occurrence of tracheitis in influenza, since destruction and damage to the delicate ciliated epithelium in this area cause the disappearance of an effective barrier to invasion of the lungs by inhaled bacteria, thus offering an explanation for the great frequency of secondary invasion of the lungs in influenza

The virus may invade the lungs by indirectly gaining access from the congested pharyngeal veins and extravasated blood in the submucosa of the postnasal region, by traveling in the form of minute infective emboli along the arterial route, and may become arrested in the terminal arterioles of the pulmonary artery.

CLINICAL VARIETIES. The clinical varieties of influenza are separated according to the manifestations of the disease. They are. (1) simple catarrhal fever, (2) pulmonary form, (3) gastrointestinal form and (4) nervous form.

Simple Catarrhal Fever. The usual early symptoms are a feeling of tightness and constriction in the thorax, disappearing with the onset of cough and expectoration Rales and rhonchi may be heard in auscultation The simple form tends to be remittent in character, the symptoms usually abating in the daytime and increasing in severity toward evening Great prostration attends the disease throughout its course, and may last for days or weeks after convalescence.

Pulmonary Form The sense of constriction in the thorax, dyspnea and stiffness, and soreness in the throat are much more intense than in the simple form The

Confirmation of the clinical diagnosis of influenza may be obtained by the demonstration of a rise in the antibody titer of serum collected during convalescence as compared with serum obtained early in the illness and by isolation of virus from nasal or pharyngeal washings It seems that many laboratory workers prefer the agglutination-inhibition test. This test is based on the fact that influenza viruses agglutinate chicken red blood corpuscles and that this capacity is specifically inhibited by immune serum

Less than a fourfold antibody response formerly was considered within the limits of experimental error The frequent occurrence of twofold increases in titer in the agglutination-inhibition test may be considered indicative of influenzal infection. However, this or any other laboratory test is not available for general diagnostic use in influenza

Differential Diagnosis There are certain types of influenza in which it is often extremely difficult to come to a diagnosis because of their marked resemblance to other infections.

Since conjunctivitis, laryngitis, bronchitis, tonsillitis and frontal headache are common to *measles* and influenza, a certain diagnosis may not be possible before the fourth day, when the fresh febrile accession and the appearance of the rash indicate measles.

Owing to the acute onset, with shivering and cough, influenza may bear a close resemblance to *central pneumonia*, from which it can be distinguished by roentgenoscopic examination of the lungs

If the attack of influenza commences with gradual pyrexia, with diarrhea, rose spots, and enlargement of the spleen, as happens occasionally, in both *typhoid fever* and influenza, the diagnosis may have to wait until the temperature begins to fall, on the third or fourth day of the illness, when the disease is recognized as influenza. Leukocytosis is absent in both diseases when uncomplicated

There is often difficulty in the differential diagnosis between the abdominal type of influenza and *acute appendicitis* In acute appendicitis there are increasing numbers of leukocytes, whereas in influenza the leukocytes are normal or decreased in number In the absence of a significant leukocyte count, the appendicular form of influenza may resemble acute appendicitis so closely as to render a correct diagnosis impossible without a period of observation too long to be safely carried out.

Primary Atypical Pneumonia. This disease, though it occurs as frequently in the older age groups as in the younger, has been the subject of written reports chiefly because of its incidence among young adults in schools, colleges and army camps

Etiology and Epidemiology A viral etiology for atypical pneumonia has been implied by the exclusive methods practiced by bacteriologists By appropriate methods materials consisting of washings from the noses of selected subjects suffering from primary atypical pneumonia have been transferred to healthy individuals These healthy individuals in due time have manifested respiratory illnesses varying in severity and clinical manifestations corresponding to those of atypical pneumonia

Epidemics of viral pneumonia occur in the fall and winter. The disease does not seem to be highly communicable. There are numerous instances, however, of contact infection from patient to nurse and from one member of a family to another. These observations suggest that often prolonged and intimate contact with patients is necessary for infection. The incubation period is from one to two days No difference has been observed in the susceptibility of the sexes

Pathology Necropsy has revealed patchy hemorrhagic bronchopneumonia with acute bronchitis and bronchiolitis

Symptoms The onset is with a cold or sore throat and cough and chilly feelings, but rarely a chill The cough is at first a dry cough. A pain through the anterior and midportion of the thorax is almost always present. The headache increases in intensity and persists throughout the febrile period The fever tends to be of an irregular type with one or two rises within the 24 hours The temperature peaks

brospinal meningitis, when, although the fluid may escape under high pressure, it is clear and does not present the characteristic cytologic features of the latter disease

Substernal pain, varying from a mild soreness to acute pain, is often associated with influenza

In the earlier stages of an epidemic, progress is rapid, and convalescence is usually established on an average of 5 days without any sequelae Later in an epidemic, both the intensity and the virulence of the disease increases, convalescence is more protracted as the febrile period lengthens, and the bronchitic infections are more pronounced

A high temperature is not a grave symptom during the first 48 hours of influenza Unfavorable symptoms are delirium, stupor, insomnia, persistent vomiting and severe diarrhea

EXAMINATION A bright flushing of the cheeks is common at the commencement of the disease

A light cyanosis is often observed on the cheeks, lips, ears and neck. This coloration is distinctly different from the darker cyanosis commonly seen in pneumonia or bronchitis In those who have capillary bronchitis it may become evident before the development of signs in the lungs

As a peculiarity in influenza, *sweating* was observed in early times, and the "sweating sickness" in the sixteenth century may have been a virulent influenza The profuse perspirations occur during the febrile period and may give rise to a curious odor, which is said to be similar to that of typhus patients Profuse odoriferous sweating is most often present in very ill patients who have influenza and must be regarded as an unfavorable symptom.

A diffusely distributed *erythema* has often been observed *Purpura* may be present as a terminal event Herpes labialis and redness and suffusion about the eyes vary in degree in each case.

A relative *slowness of the pulse* is often a common feature while the fever is at its height A sudden rise in the pulse rate indicates a serious complication

The *blood pressure* seems to be at its lowest at about the fourth or fifth day. During convalescence the blood pressure rises slowly to its normal, but may take a week or two to attain it Much of the feeling of depression and lassitude after influenza is associated with a decreased blood pressure.

There are no significant changes in the appearance of the tongue.

Vomiting usually ceases during the first 48 hours in the absence of complications or the excessive use of stimulating expectorants or sulfonamides *Diarrhea,* often associated with vomiting, is common in the first 48 hours

Epistaxis tends to be recurrent rather than obstinate and usually is not a frequent symptom If it is excessive, light packing is all that is required. If anemia should be found, it is not from nosebleed *Hemoptysis* is present if pneumonia is present

No important changes are present in the urine. It is scanty in amount, highly colored, and contains a small amount of albumin

DIAGNOSIS In the sporadic instances of the disease the diagnosis is purely clinical, supported by no other evidence The clinical features are considered to be sudden onset of fever, muscular aching, prostration and various signs of inflammation of the respiratory tract High morbidity rates, wide geographic extent, and a sharp increase in mortality from pneumonia characterize epidemics, many of which during the past century have been recognized on the basis of these criteria It is difficult to differentiate the clinical and epidemiologic characteristics of influenza from those of various other forms of respiratory disease.

Laboratory methods of diagnosis reveal that the different influenza viruses may produce a rather characteristic form of the disease, according to the foregoing criteria, as well as numerous mild atypical illnesses and obscure infections.

Hyperpnea and cyanosis are present. High fever is common in all severe cases. Rose spots occasionally appear from the seventh to the thirteenth day Leukocytosis, when it occurs, is considered to be due to secondary pneumonia from other organisms.

A clinical diagnosis is always presumptive. The presence of an atypical pneumonia or protracted fever in a patient who has a history of association with sick parrots or canaries justifies a suspicion of psittacosis Once it is suspected that the lung disease is psittacotic, a history of association with birds may be obtained. The bird is often the canary. The virus then can often be isolated by inoculation of citrated blood or sputum into mice.

The demonstration of complement-fixing antibodies is often employed to establish that a given acute illness is caused by a member of the psittacosis-lymphogranuloma group Complement-fixing antibodies may appear in the serum from 4 to 8 days after the onset of symptoms Additional serum specimens then are examined from time to time to ascertain a rise in titer within the next 4 or 5 days If there should be rise in the titer, it is significant. A serum titer of 1 16 or greater is suggestive of psittacosis if the serologic reaction for syphilis is negative and if there is no evidence of infection by the virus of lymphopathia venereum.

The mortality rate is about 1 in every 5 of those who have the disease.

DISEASES OF THE LUNGS DUE TO HIGHER ANIMAL PARASITES

The selective affinity of parasites for special tissues determines to a large extent the distribution of the lesions.

There are several parasitic worms that pass through the lungs during larval development and cause pulmonary disease, for instance, *Ascaris, Strongyloides,* hookworm, *Trichinella spiralis,* and *Echinococcus granulosus* The pulmonary invasion by *Trichinella spiralis* and *Echinococcus granulosus* may leave larvae in the lungs which may cause disease at a later date

Paragonimiasis. A parasitic trematode worm, or fluke, *Paragonimus westermani,* selects the lung as the preferred tissue of the host in which to reside, and causes the disease known as paragonimiasis.

Paragonimus westermani has a wide geographic distribution in the Orient and in South America The adult parasite has been found in mammals in Minnesota, Wisconsin, Michigan, Ohio, Mississippi, Kentucky, South Carolina and northern Canada, and in addition the larval forms have been observed in crayfish in Illinois, Indiana, Iowa, Louisiana, Missouri, Pennsylvania, Virginia, West Virginia and Ontario, Canada. Human infestation in North America, however, is rarely present

Man is infected by eating the raw or improperly cooked flesh of these crustacean hosts

The chief habitat of the adult parasite is the lungs The worms are enclosed in cystic cavities, which rupture into the bronchi, thereby permitting the ova to reach the sputum Externally the lungs show little change except scattered areas of congestion, emphysematous edges, and an uneven surface with reddish brown, superficial nodules In man these nodules usually number fewer than twenty and do not as a rule project from the surface These nodules are composed of cysts

Paragonimiasis is a slowly progressing chronic condition of insidious onset, resembling in many respects tuberculosis. Four types have been described· (1) general, (2) pulmonary, (3) abdominal and (4) cerebral

The general type is manifested by fever, enlargement of the superficial lymph nodes, especially the axillary and inguinal, with occasional cutaneous ulceration, and in cases of fatal infection, muscular rheumatic pains

In the predominating pulmonary type the patients have a chronic cough, most pronounced on rising in the morning, an abundant, blood-stained, rusty brown, purulent, tenacious sputum; and occasional attacks of hemoptysis, usually slight

tend to increase during the first few days of illness but may not reach the maximum until the eighth to the twelfth day. Rarely are there dyspnea and cyanosis.

Examination. On examination there may be a slight impairment of resonance on percussion if the lesion presents at the lung base. If the process is central, if it presents toward the axillae, or is in the upper pulmonary fields, percussion changes may not be found. Rales may be heard. Physical signs may become detectable only after the acute illness has passed Resolution of the pneumonia is often delayed for weeks This is the so-called nontubercular basilar infection of former days

In patients who present no objective physical findings the cold agglutination reaction has been found to be of some value in the diagnosis of this disease. The cold agglutination reaction is based on the presence of agglutinins which cause clumping of homologous or group O red cells at low temperatures. The test is not *infallible, since not all patients yield a positive reaction* *Furthermore, cold agglutinins* have been reported in paroxysmal hemoglobinuria, trypanosomiasis, pernicious anemia, leukemia, lymphoblastoma, cirrhosis, venous thrombosis and gangrene among others.

The leukocyte count is normal, or there may be a leukopenia. Leukocytosis if present may appear after several days. The sputum does not contain predominating bacteria Cold agglutinins appear during the second week in a majority of cases of primary atypical pneumonia and therefore are of no great diagnostic assistance

Diagnosis On general examination there may not be any pulmonary signs. Roentgenologic examination may present the first evidence of pulmonary involvement The lesion seems to begin at the hilus of the lung and spreads outward. However, in some instances roentgenologic examination does not reveal changes in the lungs during the active course of the disease. The disease is revealed after the symptoms have subsided.

In young adults the prognosis is good In older patients, whom the disease affects like bronchopneumonia, the outcome is more likely to be fatal

There is no effective treatment. Chemotherapy and antibiotic therapy are worthless or harmful

Psittacosis and Ornithosis (Psittacosis-Lymphopathia Viruses) The infective agents of psittacosis of birds and man, lymphopathia venereum of man, and murine and feline pneumonitis seem to be disease agents intermediate between the rickettsias and viruses. These belong to the so-called chlamydozoa and are gram negative organisms.

Psittacosis. Synonyms for psittacosis are ornithosis, parrot fever, psittacose, and Papageienkrankheit The avian psittacosis is caused by an elementary-body virus which develops in reticuloendothelial cells It is communicable to man.

Psittacosis is an acute and sometimes protracted febrile illness, with pulmonary lesions, which is transmitted from sick parrots to man A viral disease with similar pathologic manifestations is found in wild birds and tamed canaries, as well as in pigeons and chickens

The disease is severe, has a high mortality rate, and affects all ages and both sexes The incubation period is usually about 10 days, in exceptional cases as short as 4 or as long as 16 days

The pathologic changes observed are those of septicemia with localizing pulmonary lesions.

[illegible] There are general- [illegible] chills and rigors are [illegible] nty, mucoid, sometimes purulent, occasionally blood stained but infrequently rust colored. Abdominal pain, nausea and vomiting are common.

On examination after the fifth day of illness a few crepitant rales are present in the lungs. Later signs indicate patchy regions of consolidation in one or both lungs

the tissues become cyanotic, and peripheral edema appears. All of these changes are indicative of chronic passive congestion.

It may be inferred from the causes which originate chronic passive congestion of the lungs that essentially this process is one of chronic edema. An acute pulmonary edema may arise during the course of such a chronic passive congestion, and the latter constitutes one of the common causes of acute pulmonary edema.

Acute Pulmonary Edema. This is a serious condition which may be the immediate cause of death in cardiac and circulatory failures such as acute and chronic failure of the left ventricle, acute coronary thrombosis, angioneurotic edema, and the excessive intravenous administration of fluids Acute pulmonary edema may arise from extensive acute pulmonary disease such as pneumonia, extensive malignant metastasis, and inflammation produced by the inhalation of irritant gases.

The symptoms are the manifestations of lungs filled with fluid, with all of the anxieties and apprehensions of an individual drowning Add to this the agony of pain such as is present in the case of cardiac infarction and there is truly the combined picture of horror and death

On examination there is profound cyanosis of the face and extremities. The superficial veins of the face, neck and upper extremities are distended. The extremities are often dark and cold Pressure applied to the skin of such an extremity leaves a blanched area which remains white for some time

The vibrations from the audible rhonchi and rales are palpable. On percussion the note is flat over the posterior portions of the lower lobes There are so many noises present in the lungs that auscultation is not helpful diagnostically.

The diagnosis is usually obvious from inspection The roentgenoscopic examination often gives some clue to the physical state of the heart, lungs, pleura and mediastinum.

Pulmonary Embolism. Embolism is the sudden obstruction of the lumen of a blood vessel by a blood clot, air, fat or any other substance which has been brought to its place by the blood current.

The commonest embolus reaching the larger pulmonary arteries is composed of clotted blood. Such blood clots may arise in the heart affected by valvular heart disease, or in the larger veins, usually those of the legs. In the leg veins there are two conditions prone to create emboli These conditions are phlebothrombosis and phlebitis. In phlebothrombosis there is no evidence of antecedent disease or injury of the vein. Thrombosis is first. The phlebitis develops as a reaction to the thrombosis

Embolism, usually in the lungs, is the most serious complication of postoperative venous thrombosis. It is often the result of phlebothrombosis and occurs in many cases in which there is no clinical evidence of thrombophlebitis Therefore it is assumed that thrombosis has occurred in some one of the peripheral veins and that either the entire thrombus became the embolus, or the part of it which remained at the original site failed to produce local symptoms.

Surgical exploration for inoperable carcinoma associated with metastasis is accompanied with high incidence of postoperative pulmonary embolism. Usually the magnitude of the surgical procedure is directly related to the frequency of embolism, which is twice as common after repair of bilateral hernia as after operations for unilateral hernia

When pulmonary embolism occurs after the clinical manifestations of thrombophlebitis have appeared, the emboli are likely to be small and nonfatal. It is commoner to observe phenomena of pulmonary embolism a few days before clinical thrombophlebitis than after the symptoms of thrombophlebitis have appeared.

though at times severe. The physical signs may suggest lobular pneumonia or tuberculosis.

A definite diagnosis is established by finding the ova in the sputum, the feces or in the cutaneous or subcutaneous tissues of a patient who has pulmonary disease.

In light infections prognosis is good, although spontaneous cure may not occur. *In heavy invasions*, superimposed tuberculosis, secondary pyogenic infections, or cerebral involvement the prognosis is unfavorable.

Echinococcus Cysts of the Lungs. Echinococcus cysts of the lungs are caused by *Echinococcus granulosus*, of the superfamily Taenioidae.

The symptoms, if any are present, are cough, hemoptysis, dyspnea and pain. The cough is dry and hacking and may be accompanied by slight mucoid expectoration Hemoptysis in small quantities may occur. Mild thoracic discomforts, but rarely pain unless the pleura is reached, may develop, as may a pleural rub also. In pleural involvement there may be a low-grade fever The cyst may give pressure symptoms which are followed by rupture into a bronchus, or it may penetrate the pericardium, a chamber of the heart, the vena cava or the thoracic wall

The rupture of a cyst into the bronchial tree originates sudden distress, pain and the expectoration of quantities of thin, blood-stained fluid If the patient survives the rupture, the diagnosis of hydatid cyst becomes evident as fragments of cyst are coughed up After rupture, urticaria is common. Sudden death has followed the impaction of fragments of the cyst in the glottis. Profuse hemoptysis may occur at the time of rupture or later and may prove fatal

On examination over the cyst fremitus is diminished or absent. Percussion dullness may be elicited There is often displacement of mediastinal structures Auscultation may reveal changes in respiratory sounds because of the space-occupying cyst Crackling or musical rales are common Occasionally percussion and auscultation may be altered by the effects of a bronchial communication. Roentgenologic examination reveals the cysts

The diagnosis is made by identification of the parasite or the cysts The intradermal and the complement fixation tests may be helpful The clinical manifestations and the roentgenologic evidence are often diagnostic Puncturing and aspiration of the cysts are contraindicated because of the danger of rupture and anaphylactic phenomena. If the situation of the cyst is favorable for surgical approach, operation should be considered

DISEASES OF THE LUNGS SECONDARY TO CIRCULATORY DISTURBANCES

Acute and Chronic Pulmonary Congestion. Acute and chronic pulmonary congestion occurs in certain primary and secondary diseases of the lungs The primary diseases of the lungs which are characterized by acute congestion are the acute infections and the acute injuries from physical and chemical agents. Acute congestion from primary disease of the lungs may be localized, as in the pneumococcal pneumonias, or generalized when provoked by the inhalation of an irritating gas

Chronic congestion of the lungs occurs less frequently from primary pulmonary disease than it does from disease in which the lungs are secondarily congested, as in heart failure from disease of the mitral valves. Chronic passive congestion of the lungs, as it occurs in mitral heart disease, renders the lungs less elastic and more rigid than normal. The lining of the bronchial tubes is malnourished and desquamates and thus permits fluid and erythrocytes to exude from the capillaries into the air passages to be expectorated. Cough and increased expectoration may be the only complaint that a patient has for seeking help However, before long the patient has dyspnea and the sputum becomes reddish brown (rusty) in color, the peripheral veins are dilated, the capillaries are widened and pulsate, the skin of the lips and

the tissues become cyanotic, and peripheral edema appears. All of these changes are indicative of chronic passive congestion.

It may be inferred from the causes which originate chronic passive congestion of the lungs that essentially this process is one of chronic edema. An acute pulmonary edema may arise during the course of such a chronic passive congestion, and the latter constitutes one of the common causes of acute pulmonary edema.

Acute Pulmonary Edema. This is a serious condition which may be the immediate cause of death in cardiac and circulatory failures such as acute and chronic failure of the left ventricle, acute coronary thrombosis, angioneurotic edema, and the excessive intravenous administration of fluids Acute pulmonary edema may arise from extensive acute pulmonary disease such as pneumonia, extensive malignant metastasis, and inflammation produced by the inhalation of irritant gases

The symptoms are the manifestations of lungs filled with fluid, with all of the anxieties and apprehensions of an individual drowning Add to this the agony of pain such as is present in the case of cardiac infarction and there is truly the combined picture of horror and death

On examination there is profound cyanosis of the face and extremities. The superficial veins of the face, neck and upper extremities are distended. The extremities are often dark and cold Pressure applied to the skin of such an extremity leaves a blanched area which remains white for some time.

The vibrations from the audible rhonchi and rales are palpable. On percussion the note is flat over the posterior portions of the lower lobes. There are so many noises present in the lungs that auscultation is not helpful diagnostically.

The diagnosis is usually obvious from inspection. The roentgenoscopic examination often gives some clue to the physical state of the heart, lungs, pleura and mediastinum.

Pulmonary Embolism. Embolism is the sudden obstruction of the lumen of a blood vessel by a blood clot, air, fat or any other substance which has been brought to its place by the blood current

The commonest embolus reaching the larger pulmonary arteries is composed of clotted blood Such blood clots may arise in the heart affected by valvular heart disease, or in the larger veins, usually those of the legs In the leg veins there are two conditions prone to create emboli These conditions are phlebothrombosis and phlebitis In phlebothrombosis there is no evidence of antecedent disease or injury of the vein Thrombosis is first. The phlebitis develops as a reaction to the thrombosis

Embolism, usually in the lungs, is the most serious complication of postoperative venous thrombosis It is often the result of phlebothrombosis and occurs in many cases in which there is no clinical evidence of thrombophlebitis Therefore it is assumed that thrombosis has occurred in some one of the peripheral veins and that either the entire thrombus became the embolus, or the part of it which remained at the original site failed to produce local symptoms.

Surgical exploration for inoperable carcinoma associated with metastasis is accompanied with high incidence of postoperative pulmonary embolism Usually the magnitude of the surgical procedure is directly related to the frequency of embolism, which is twice as common after repair of bilateral hernia as after operations for unilateral hernia

Thrombophlebitis predisposes to pulmonary embolism, but there are reasons for believing that the clinical manifestations of peripheral thrombophlebitis are associated with fixation of the thrombus by inflammation.

When pulmonary embolism occurs after the clinical manifestations of thrombophlebitis have appeared, the emboli are likely to be small and nonfatal. It is commoner to observe phenomena of pulmonary embolism a few days before clinical thrombophlebitis than after the symptoms of thrombophlebitis have appeared

Allen, Barker and Hines have stated that when a patient has a pulmonary embolism after operation and survives, there is a 43 8 per cent chance of another thrombotic episode, a 30.5 per cent chance of another embolism and an 18.3 per cent chance of a fatal embolism in the same postoperative convalescence. The incidence is less in cases of thrombophlebitis than in cases of phlebothrombosis but is still definitely higher than in all postoperative cases as a group

Pulmonary embolism affects men much more frequently than women, despite the preponderance of operations on the lower part of the abdomen among women.

SYMPTOMS. The symptoms depend on the amount of lung tissue which is incapacitated by the occluded artery. The occlusion of a small pulmonary artery may occur without noticeable symptoms. The occlusion of a relatively large pulmonary artery produces cor pulmonale and shock. The occlusion of a large or several small pulmonary arteries may be immediately fatal

On occasion the patient who has a pulmonary embolism will have a sudden feeling of apprehension, anxiety, palpitation and dyspnea. These symptoms are often so severe that the patient is fearful of moving. The duration of the attack is often from 15 to 30 minutes Several hours or a day or two elapse before pleuritic pain or hemoptysis occurs.

Pleuritic pain which occurs in about one week to 10 days after an operation is often caused by pulmonary embolism. A distinctive feature of pulmonary embolism often is dyspnea out of proportion to restriction of respiratory movements and associated pain The pain occurs as the result of the embolus reaching a peripheral pulmonary artery and thus involving the pleura Despite pain a small embolus gives no general symptoms, and the patient maintains a sense of well-being

Hemoptysis occurring after operation should be regarded as evidence of pulmonary embolism The patient coughs up small blood clots or expectorates a thick, bloody sputum As time passes, the coughed-up blood becomes darker and decreases in amount

Small pulmonary emboli with minimal or no symptoms often occur. This occurrence indicates that the patient is susceptible to thrombosis and resultant embolism. Once this process is initiated, it will recur often and there is danger of subsequent massive pulmonary embolism

In *massive pulmonary embolism* there is an initial shock. The initial shock of a large pulmonary embolus may be survived and if so a prolonged febrile illness may follow The illness results from a large pulmonary infarct which may or may not break down to produce pulmonary abscess. This condition resembles pneumonia and is difficult to differentiate from pneumonia

EXAMINATION. The findings on physical examination after pulmonary embolism are exceedingly variable and often inconclusive. Rales, percussion dullness and pleuritic friction sounds are irregularly present in the beginning As time passes the physical signs of a localized pneumonia may appear. The presence of unilateral pleural effusion after a surgical operation is highly suggestive that pulmonary embolism has occurred

Examination soon after a large pulmonary embolus has occurred reveals evidence of shock In smaller but definitely manifested emboli there are present dyspnea, perhaps orthopnea, and always varying degrees of apprehension If a large area of the lung has been embolized there is an increased pulsation in the second and third interspaces to the left of the sternum and a loud systolic murmur with accentuation of the second pulmonic sound Gallop rhythm is present occasionally. The veins of the neck are dilated and pulsating. There is an initial fall of temperature and then a rise to 101 or 103 F (38.3 or 39 4 C) as the evident degree of shock abates. There may be scattered or numerous moist rales in the lungs, and the breath sounds may be distant or suppressed over the affected portion of the

lung. Signs of the local accumulation of fluid in the pleural space may develop after a few days. Rather severe and persistent hemoptysis often is evident.

There is no characteristic roentgenographic evidence of a large pulmonary infarct. Large infarcts frequently produce elevation of the diaphragm on the affected side, indefinite thickening of the pleural shadow in the costophrenic angle and occasionally the appearance of a small amount of pleural fluid

Electrocardiographic changes which are indicative of acute cor pulmonale occurring with severe pulmonary embolism may be present The changes in the electrocardiogram may develop at any time during the first 48 hours after the embolism occurs, and they may be transient, but when they are found they are significant (Barnes).

A large pulmonary embolus is one of the causes of sudden death. Some patients may live for a few minutes after the episode or, more rarely, a few hours may elapse before death occurs.

Diagnosis. The occurrence of sudden pleural pain from 6 to 21 days after an operation, obstetric delivery or severe injury should be regarded with great suspicion since other conditions causing pleurisy are rare in those periods Sudden death occurring in the same group of patients during the same interval should be considered as most likely the result of a large pulmonary embolus, particularly if the clinical course has otherwise been normal If pleural pain, hemoptysis and shock, as produced by a relatively large pulmonary embolus, occur in a patient who has acute or recent thrombophlebitis, the diagnosis of embolism can almost certainly be made, but as has been stated, most embolisms occur before thrombophlebitis is clinically evident.

The one condition difficult at times to differentiate is an acute coronary thrombosis. The electrocardiogram is of great value in distinguishing acute coronary thrombosis from pulmonary embolism since the patterns are different even if the coronary thrombus is in the posterior descending branch. In coronary thrombosis frequently the pain is more severe, it is not pleural, it often extends to the arms or shoulders, cyanosis is infrequent, and signs of a localized pulmonary lesion are absent.

The electrocardiographic changes in infarction of the posterior ventricular wall and those present in pulmonary embolism are somewhat similar The deep S and the inversion of the T waves present after pulmonary embolism do not occur in infarctions of the posterior ventricular wall.

The signs and symptoms of small pulmonary infarcts usually disappear within a week with the possible exception of some residual elevation of the diaphragm on the affected side.

Air Embolism. Air embolism may occur in two forms (1) pulmonary venous air embolism and (2) arterial air embolism

In the pulmonary form, air enters one of the systemic veins and is carried to the right side of the heart and pulmonary circulation and depends for its effects on mechanical obstruction of the outflow channel of the right ventricle.

In arterial embolism the air gains entrance to the pulmonary venous channels and is propelled from the left ventricle to those systemic arteries which supply the superiorly located portions of the body Since a small amount of air can effectively block a medium-sized artery, serious consequences may result when a few milliliters of air enter the pulmonary vein and are carried into either the coronary or cerebral circulation or both

In the pulmonary form the presence of air in the right ventricle produces a loud, churning sound, often readily heard without stethoscopic aid, which is known as the millwheel murmur This murmur appears almost immediately after air has entered the venous circulation

expectoration are absent except when conditions such as bronchial infections or asthma are present Cyanosis and compensatory polycythemia may appear

EXAMINATION. Inspection in severe emphysema reveals the thorax permanently in the position of deep inspiration with slight movements of the thoracic wall; the phrenic wave sign is absent The lungs have lost their elastic recoil so that the intercostal and abdominal muscles are used for breathing. Owing to the voluminous lungs the diaphragm is stretched and its function is impaired Therefore the neck and *intercostal muscles* may actively support inspiration. The action of the latter muscles pulls the thoracic wall upward and forward. The expanded lungs extend into the pleural sinuses and between the heart and thoracic wall, resulting in increase of the anteroposterior diameter of the thorax and dorsal kyphosis.

If the emphysema is severe, cyanosis may be observed and the veins of the neck are distended In some cases there is clubbing of the fingers and toes.

On palpation decreased expansion of the thoracic wall and diminished tactile fremitus are evident The percussion note is hyperresonant and the lower margins of the lungs extend below their normal limits. The area of cardiac dullness is diminished and the liver is in a low position On auscultation the expiratory phase of respiration is prolonged and low-pitched Whispered voice sounds are diminished Rales are elicited only when other conditions such as asthma and bronchitis are present

DIAGNOSIS The appearance of the patient, in combination with the physical and roentgenologic findings, is diagnostic.

Many persons endure emphysema over long periods of time.

Senile Emphysema. Elderly persons who have kyphosis of the thoracic vertebrae and some who do not have deformities of the spinal column may have a general narrowing of the thorax and the intercostal spaces and a decrease in the respiratory movements of the thoracic wall without symptoms

On examination, tactile fremitus is diminished, the percussion note is hyperresonant, and auscultation reveals diminished breath sounds. Often only the expiratory phase of respiration is heard

The diagnosis is made during routine physical examinations.

Traumatic or Interstitial Emphysema. Rupture of alveolar walls may result from needle puncture, crushing or tearing injuries of the chest, violent coughing, and from the use of a pulmotor Interstitial emphysema may develop in those who are enjoying health without evidence of disease (spontaneous interstitial emphysema)

The escaped air from the lung may spread through the interstitial tissue and through the hilus and thence into the mediastinum (*mediastinal emphysema*); thence it may spread into the tissues of the neck and occasionally gives rise to generalized, subcutaneous emphysema

SYMPTOMS. When the amount of air is small, there are no symptoms When a large amount of air escapes, some of it may dissect along the connective tissue bands surrounding the blood vessels and form blebs on the pleura. When a bleb ruptures, spontaneous pneumothorax occurs.

In some instances the first symptom is severe pain beneath the sternum or in the side of the thorax The pain may extend to the left side of the neck and down the left arm. The pain of spontaneous interstitial emphysema disappears soon after the attack

EXAMINATION. The late Louis Hamman described, as being characteristic of this condition, a peculiar crackling, crunching sound heard over the sternum and precordium which is synchronous with the heart beat This sound may be heard with *the patient* in any position, but it is more likely to be elicited when the patient lies on the left side or leans forward. These sounds convey the impression of air being churned or squeezed in the tissues. Often they are so loud that they can be heard by the patient. Interstitial emphysema causes a hyperresonant note to percussion over

the usual region of cardiac dullness. In some cases signs of spontaneous pneumothorax occur.

DIAGNOSIS. The history and the examination by physical means are diagnostic. The results of roentgenologic examination are negative unless pneumothorax is present

Symptoms soon disappear.

TUMORS OF THE LUNG

Tumors of the lung may be arranged in certain groups based partly on the manner of origin and partly on the tissue from which the tumor originates (1) Bronchial malformations may be productive of benign cystic and papillary structures. The congenital cystic malformations are of two types. (a) overgrowth of misplaced fetal portions of the bronchial tree and (b) overgrowth of areas of fetal bronchiectasis resulting from inflammation and leading to occlusion of a bronchus and retention of mucus (2) Mixed tumors, also of fetal origin, arise from fetal pulmonary tissues which fail to develop into normal pulmonary structures These tumors may be designated as chondromas or sarcomas. When the epithelial elements predominate they are termed adenoma, alveolar carcinoma or adenocarcinoma. Hamartoma of the lung may contain cartilage and is thus related to the chondromas. However, not all hamartomas contain cartilage. (3) The myxomas and fibromas of the periphery of the lung probably arise from the pleura. (4) The solid diffuse carcinomas which arise as a sequel or incident to inflammations such as a chronic tuberculous pneumonia are difficult to separate from bronchial carcinoma.

Regardless of the origin of lung tumors which may be classified as being benign tumors, they are comparatively rare The so-called bronchial adenoma and the chondroma or hamartoma are the commonest benign tumors of the lung.

The detection of these lung tumors is accomplished by roentgenologic examination The diagnosis awaits histologic study The prognosis, of course, depends on the degree of anaplasia of the cells

Metastatic Malignant Disease of the Lung. Metastatic malignant lesions of the lungs are many times more frequent than primary ones

Epithelial Malignant Lesions. Carcinomas, hypernephromas and chorionepitheliomas almost always give secondary pulmonary involvement. Carcinomas of the breast frequently metastasize to the lungs Malignant lesions of the thyroid gland, air passages, alimentary tract and its associated glands, the urinary organs, genitalia and extremities often aid in the destruction of the patient through metastasis to the lungs.

Pulmonary metastasis occurs by (1) direct extension, (2) blood stream implantation and (3) lymphatic spread The metastatic lesions usually involve the lower portions of the lungs They appear as (1) single or multiple nodular growths in one or both lungs and (2) infiltrative or diffuse growths in both lungs. A lung is more completely filled with secondary malignant disease in instances of extension from cancer of the breast than in extension from cancer elsewhere The affected lung usually corresponds to the breast involved by carcinoma The pleura is often extensively involved, as shown by a hemorrhagic or serofibrinous effusion

SYMPTOMS A few who have metastatic pulmonary carcinoma may have cough, vague thoracic discomforts and at times pleuritic pain Dyspnea may be a distressing symptom and hemoptysis is common However, on roentgenologic examination the lungs are frequently found to be involved without there having been any symptoms or findings on examination of the thorax by physical means.

EXAMINATION. In early periods of metastatic pulmonary tumors there may be observed a suppression of the breath sounds, especially pronounced during inspiration and sometimes accompanied by fine crackling rales over a limited area of the thorax. As the tumor or tumors grow, decreased expansion ensues The percussion

expectoration are absent except when conditions such as bronchial infections or asthma are present Cyanosis and compensatory polycythemia may appear.

EXAMINATION. Inspection in severe emphysema reveals the thorax permanently in the position of deep inspiration with slight movements of the thoracic wall; the phrenic wave sign is absent. The lungs have lost their elastic recoil so that the intercostal and abdominal muscles are used for breathing. Owing to the voluminous lungs the diaphragm is stretched and its function is impaired. Therefore the neck and intercostal muscles may actively support inspiration. The action of the latter muscles pulls the thoracic wall upward and forward The expanded lungs extend into the pleural sinuses and between the heart and thoracic wall, resulting in increase of the anteroposterior diameter of the thorax and dorsal kyphosis.

If the emphysema is severe, cyanosis may be observed and the veins of the neck are distended In some cases there is clubbing of the fingers and toes.

On palpation decreased expansion of the thoracic wall and diminished tactile fremitus are evident The percussion note is hyperresonant and the lower margins of the lungs extend below their normal limits The area of cardiac dullness is diminished and the liver is in a low position On auscultation the expiratory phase of respiration is prolonged and low-pitched Whispered voice sounds are diminished. Rales are elicited only when other conditions such as asthma and bronchitis are present.

DIAGNOSIS The appearance of the patient, in combination with the physical and roentgenologic findings, is diagnostic.

Many persons endure emphysema over long periods of time

Senile Emphysema. Elderly persons who have kyphosis of the thoracic vertebrae and some who do not have deformities of the spinal column may have a general narrowing of the thorax and the intercostal spaces and a decrease in the respiratory movements of the thoracic wall without symptoms

On examination, tactile fremitus is diminished, the percussion note is hyperresonant, and auscultation reveals diminished breath sounds *Often only the expiratory phase of respiration is heard.*

The diagnosis is made during routine physical examinations

Traumatic or Interstitial Emphysema. Rupture of alveolar walls may result from needle puncture, crushing or tearing injuries of the chest, violent coughing, and from the use of a pulmotor Interstitial emphysema may develop in those who are enjoying health without evidence of disease (spontaneous interstitial emphysema)

The escaped air from the lung may spread through the interstitial tissue and through the hilus and thence into the mediastinum (mediastinal emphysema); thence it may spread into the tissues of the neck and occasionally gives rise to *generalized, subcutaneous emphysema*

SYMPTOMS When the amount of air is small, there are no symptoms. When a large amount of air escapes, some of it may dissect along the connective tissue bands surrounding the blood vessels and form blebs on the pleura. When a bleb ruptures, spontaneous pneumothorax occurs

In some instances the first symptom is severe pain beneath the sternum or in the side of the thorax The pain may extend to the left side of the neck and down the left arm. *The pain of spontaneous interstitial emphysema* disappears soon after the attack

EXAMINATION. The late Louis Hamman described, as being characteristic of this condition, a peculiar crackling, crunching sound heard over the sternum and precordium which is synchronous with the heart beat. This sound may be heard with the patient in any position, but it is more likely to be elicited when the patient lies on the left side or leans forward. These sounds convey the impression of air being churned or squeezed in the tissues. *Often they are so loud that they can be heard by the patient.* Interstitial emphysema causes a hyperresonant note to percussion over

the usual region of cardiac dullness. In some cases signs of spontaneous pneumothorax occur.

DIAGNOSIS. The history and the examination by physical means are diagnostic. The results of roentgenologic examination are negative unless pneumothorax is present.

Symptoms soon disappear.

TUMORS OF THE LUNG

Tumors of the lung may be arranged in certain groups based partly on the manner of origin and partly on the tissue from which the tumor originates. (1) Bronchial malformations may be productive of benign cystic and papillary structures. The congenital cystic malformations are of two types (a) overgrowth of misplaced fetal portions of the bronchial tree and (b) overgrowth of areas of fetal bronchiectasis resulting from inflammation and leading to occlusion of a bronchus and retention of mucus. (2) Mixed tumors, also of fetal origin, arise from fetal pulmonary tissues which fail to develop into normal pulmonary structures These tumors may be designated as chondromas or sarcomas When the epithelial elements predominate they are termed adenoma, alveolar carcinoma or adenocarcinoma. Hamartoma of the lung may contain cartilage and is thus related to the chondromas. However, not all hamartomas contain cartilage (3) The myxomas and fibromas of the periphery of the lung probably arise from the pleura (4) The solid diffuse carcinomas which arise as a sequel or incident to inflammations such as a chronic tuberculous pneumonia are difficult to separate from bronchial carcinoma.

Regardless of the origin of lung tumors which may be classified as being benign tumors, they are comparatively rare The so-called bronchial adenoma and the chondroma or hamartoma are the commonest benign tumors of the lung.

The detection of these lung tumors is accomplished by roentgenologic examination. The diagnosis awaits histologic study The prognosis, of course, depends on the degree of anaplasia of the cells

Metastatic Malignant Disease of the Lung. Metastatic malignant lesions of the lungs are many times more frequent than primary ones.

Epithelial Malignant Lesions. Carcinomas, hypernephromas and chorionepitheliomas almost always give secondary pulmonary involvement Carcinomas of the breast frequently metastasize to the lungs Malignant lesions of the thyroid gland, air passages, alimentary tract and its associated glands, the urinary organs, genitalia and extremities often aid in the destruction of the patient through metastasis to the lungs.

Pulmonary metastasis occurs by (1) direct extension, (2) blood stream implantation and (3) lymphatic spread. The metastatic lesions usually involve the lower portions of the lungs They appear as (1) single or multiple nodular growths in one or both lungs and (2) infiltrative or diffuse growths in both lungs A lung is more completely filled with secondary malignant disease in instances of extension from cancer of the breast than in extension from cancer elsewhere The affected lung usually corresponds to the breast involved by carcinoma The pleura is often extensively involved, as shown by a hemorrhagic or serofibrinous effusion

SYMPTOMS. A few who have metastatic pulmonary carcinoma may have cough, vague thoracic discomforts and at times pleuritic pain. Dyspnea may be a distressing symptom and hemoptysis is common However, on roentgenologic examination the lungs are frequently found to be involved without there having been any symptoms or findings on examination of the thorax by physical means

EXAMINATION. In early periods of metastatic pulmonary tumors there may be observed a suppression of the breath sounds, especially pronounced during inspiration and sometimes accompanied by fine crackling rales over a limited area of the thorax. As the tumor or tumors grow, decreased expansion ensues. The percussion

note then becomes flat, and bronchovesicular or bronchial breathing and sibilant and sonorous rales are present. Signs of pleural effusion may be found early or at least during the course of the disease. These signs are usually manifest over the lower half of the lungs particularly.

DIAGNOSIS. Roentgenologic examination is usually diagnostically conclusive It is well to try to confirm the diagnosis, if possible, by repeated cytologic examinations of the sputum. Bronchoscopy is of little or of no diagnostic value.

Sarcomas. Metastatic involvement of the lungs by sarcomatous tumors is proportionately commoner than by carcinomatous tumors Sarcomas arising in almost any part of the body metastasize and secondarily involve the lungs

SYMPTOMS In metastatic pulmonary sarcoma, as in other pulmonary malignant diseases, both primary and secondary, cough, pain in the thorax, dyspnea and hemoptysis are the usual symptoms

EXAMINATION. When metastatic nodules have attained considerable size in the lungs, dullness or flatness to percussion is elicited. Sibilant and sonorous or musical rales are heard, and the breath sounds are decreased and changed to a bronchial tone. Massive growths obliterate all resonance, breath sounds and vocal fremitus or transmission of voice sounds over an entire lung field or over most of the thorax, even in the absence of sufficient fluid to produce such signs. In some cases bulging or retraction of the thorax or the intercostal spaces may be visible.

DIAGNOSIS The presence of metastatic pulmonary malignant disease in a patient known to have a sarcomatous tumor in any part of the body is assumed to be pulmonary sarcoma unless proved to be otherwise. The physical signs and the roentgenoscopic findings are diagnostic of a malignant tumor of the lung only, not of the type of tumor

10

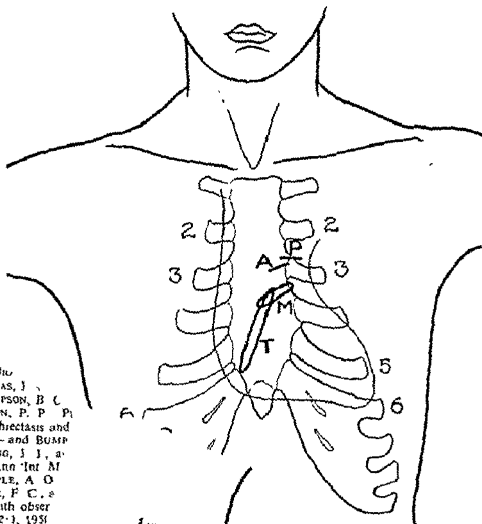
DISORDERS OF THE HEART, BLOOD PRESSURE, PULMONARY ARTERIES AND THORACIC AORTA

THE HEART

The average adult heart measures about 5 inches (12 7 cm.) in length, 3 inches (7.6 cm.) in width, and 2½ inches (6 4 cm) in thickness The average weight of the healthy adult heart of a man is about 9 ounces (280 gm) and of a woman, 8 ounces (250 gm) These weights may be doubled in instances of cardiac enlargement.

Outlines of the Heart. The base or upper margin of the heart, from which the great vessels go off, lies in the second intercostal space or at the upper margin of the third rib behind the sternum It is here that the superior vena cava ends and the aorta begins. The base of the heart extends from about ½ inch (1 3 cm.) to the right of the sternum to about 1 inch (2 5 cm) to the left of the sternum.

The *right margin* of the heart, formed by the right atrium, lies from about 1½ to 1¾ inches (3.8 to 4 5 cm) to the right of the median line, at the upper border of the third costal cartilage, and extends in an outwardly curved line to the junction of the seventh rib and the sternum In the fourth interspace it may reach 1 inch (2 5 cm) beyond the right edge of the sternum



The *left margin* of the heart passes somewhat obliquely downward, from 1 inch (2.5 cm) to the left of the sternum at the upper border of the third costal cartilage, and to the left to the region of the apex

The curved sternocostal surface of the heart, which proceeds upward and forward and comes into direct contact with the anterior wall of the thorax, is formed chiefly by the right atrium and the right ventricle, it lies just behind the sternum and behind the anterior extremities of the third, fourth, fifth and sixth ribs, being in part overlapped by the margins of the lungs

The *lower margin* of the heart passes from the seventh right chondrosternal junction across the sternoxiphoid joint outward in the fifth interspace to the apex beat, which is from 1⅗ to 2 inches (4 1 to 5 1 cm.) below and to the inner side of the nipple and about 3½ inches (8.9 cm) to the left of the median line. This marks the extreme left limit of the heart. In children the apex is higher in the fourth interspace In old people it is lower

The diaphragmatic surface of the heart, posterior and inferior, is almost flat where it is in contact with the diaphragm The left atrium lies at the back of the heart and is directed toward the esophagus and spinal column, the left ventricle lies behind and below, only a small portion of it projecting forward to form the apex of the heart The auricle of the left atrium is in contact with the anterior wall of the thorax close to the pulmonary artery The orifice of the pulmonary artery is situated at the sternal end of the third left intercostal space; the orifice of the aorta lies just below the middle of the left half of the sternum at the same level The center of the mitral orifice lies behind the third left intercostal space close to the sternum, and the center of the tricuspid orifice lies behind the right half of the sternum at the level of the sternal end of the fourth intercostal space (Fig 10-1).

The atrioventricular (auriculoventricular) groove or line of junction between the atria (auricles) and ventricles runs from the sixth right chondrosternal junction upward and to the *left* to the *third* left chondrosternal junction. The atria lie above and to the right of this line, and the ventricles below and to the left.

The position and size of the heart may be determine...

of examination: (1) the inspection and palpation of the apex beat of the heart, (2) the percussion of the cardiac dullness, and (3) the delimitation of the margins of the heart by means of roentgenologic examination.

POSITION OF THE APEX BEAT OF THE HEART. In the healthy and not too fat man an elevation of the thoracic wall, at regular intervals, at the times of the systoles of the left ventricle, can be seen and felt in the left fifth intercostal space between the mammillary and the parasternal lines. When the heart is enlarged, the apex beat changes its position; it may occupy the sixth, seventh or eighth interspace instead of the fifth, and may be as far as 2 or 3 inches (5.1 to 7 6 cm.) to the left of the nipple line.

The site of the apex beat is the most lateral and the lowest part of the area of pulsation. The apex beat thus recorded, according to H. L Smith, does actually correspond to the position of the heart's apex. Thus the point of maximal impulse (p m i.) is almost always at the site of the apex beat

The position of the apex beat with the patient standing is practically the same as in the recumbent position On deep inspiration, the apex beat may descend and lie behind the sixth rib or in the sixth intercostal space; on deep expiration, in the young and healthy person, it may rise as high as the fourth intercostal space and become more diffuse. The position changes when the patient lies on his left side; it may then reach the mammillary line or, often, a point to the left of it. After rapid emaciation this mobility may be greater, when the patient lies on his right side, the apex is very little displaced to the right, rarely passing to the right of the left parasternal line.

The position of the apex beat varies somewhat with the shape of the thorax in the different somatic types and as the results of thoracic deformities. Anything that lowers the diaphragm lowers the apex beat also, anything that raises the level of the diaphragm (meteorism, ascites, pregnancy, abdominal tumors) will raise the position of the apex beat. Fluid or air in one pleural cavity will displace the apex beat toward the opposite side; retraction of a lung may have an opposite effect Enlargement of the left ventricle displaces the apex downward and to the left, enlargement of the right ventricle displaces the apex to the left but not downward A pericardial effusion may displace the apex beat upward to the third intercostal space.

Too much stress should not be laid on slight abnormalities in the position of the apex beat. Its determination, however, is the first step in the attempt to ascertain the position and size of the heart, inasmuch as the position of the apex indicates the situation of the left margin of the heart.

Precordial boss and voussure are the names given to a unilateral bulging occupying the precordial area in children This bulging is due to enlargement of the heart or to pericardial effusion The enlargement is oval, its long diameter being vertical and extending from the third to the sixth rib near the sternum It can arise only in early life while the ribs are still flexible.

PERCUSSION OF AREAS OF CARDIAC DULLNESS By percussion on the anterior surface of the thorax, the area of cardiac dullness often can be outlined, particularly in young and healthy persons Two areas of cardiac dullness may be delineated These areas are (1) that of the superficial, small cardiac dullness, and (2) that of the deep, or relative, cardiac dullness The area of small dullness corresponds to the part of the sternocostal surface of the heart not covered by the lungs, while the [illegible]
The [illegible]
of t [illegible]
this area the characteristic resonant pulmonary note is absent. The larger area of relative dullness is outlined by percussing from the lungs toward the heart and marking the points at which the percussion note becomes less resonant or relatively

dull. Though the heart is covered by the lungs at its periphery, the change in the percussion sound elicited after practice and experience permits the determination of approximate outlines of the heart with reasonable accuracy. The determination of the superficial dullness is much easier than determination of the deep dullness; for the latter a degree of skill, obtainable only by considerable practice, is required

In obesity and in emphysema the determination of the relative dullness is difficult if not impossible. The area obtained is much smaller than that corresponding to the true dimensions of the heart When the dullness passes to the right as far as the right parasternal line or farther, and upward as high as the second rib, while the left margin of the heart is as far as, or farther to the left than normal, it is certain that the heart is enlarged

Dilatation, principally of the left ventricle, causes an expansion of the area of dullness toward the left only. Dilatation of the right ventricle displaces the right margin of the area of relative dullness to the right. When both relative and absolute dullness are increased to the right of the sternal margin, there is usually either a dilatation of the right atrium or a pericardial exudate.

The apparent area of cardiac dullness as outlined by percussion may not be cardiac dullness at all but may result from the presence of tumors in the neighborhood, of pleural effusions, or of infiltrations of the lungs. Similarly, a dislocation of a heart of normal size by a pleural effusion, by a tumor, or by a pneumothorax may simulate an abnormal position of one cardiac boundary due to enlargement.

Diminution of the Area of Dullness. Seldom does this indicate diminution in size of the heart, often it is due to emphysema.

The percussion of the heart is a subjective method of measuring the heart which has much value, though the error is often considerable A high degree of accuracy in percussion is impossible for many reasons. There are no sharp margins of cardiac dullness to be obtained by percussion in the various intercostal spaces No outlines of the heart by percussion are as important diagnostically as the finding of a well-defined point of maximal impulse. The value, then, of percussion of the heart lies mainly in enabling confirmation of the suspected left limits of the heart when the impulse is ill-defined. This feat is often of enough value to reward for the time spent in the practice of percussion, and much time is required

Normal and Abnormal Sounds Over the Heart and Vessels Obtained on Auscultation. In health and in disease oscillations arise in the heart and blood vessels that may cause audible sounds. These can be recognized by listening with the naked ear or with the aid of the stethoscope

THE HEART SOUNDS If the ear or a stethoscope is placed over the thorax in the cardiac region of a healthy person, pairs of sounds are heard recurring at regular intervals Each pair of sounds consists of a first and a second sound, separated from each other by a brief interval Each pair of sounds in turn is separated from the next pair by a longer interval The duration and accentuation of the single sounds at the apex of the heart are found to be somewhat different from the duration and accentuation at the base; thus at the base and over the lower part of the sternum the first sound is longer and more accentuated, phonetically indicated as *lúbb-dupp*, whereas at the apex the second sound is more accentuated, the rhythm becoming that of *lubb-dúpp*. The first sound of each pair is synchronous with the apex beat of the heart. The second sound occurs at the very beginning of ventricular diastole. The long pause separating consecutive pairs is diastolic in time.

Origin of the Normal Heart Sounds. The origin of the *first sound* has been shown by H. L. Smith, Essex and Baldes to be chiefly due to closure of the mitral and tricuspid valv[illegible] is an element of intracardial tension tone due to oscillations [illegible] ions of the walls of the ventricles, it is less important in aus[illegible]

The *second sound* is coincident with and due to the closure and tension of the semilunar valves of the aorta and pulmonary artery at the beginning of diastole.

In children and young adults occasionally the trained ear may hear a *third sound*, audible just after the second sound It is said to be best heard at or near the apex when the patient is somewhat turned to the left side.

Auscultation Sites. The sites selected for auscultation are those at which the vibration of the particular valves in question is best heard. These auscultation sites for the pulmonary and tricuspid valves correspond to anatomic projections of the valves. The auscultation sites for the aortic and mitral valves do not correspond to the surface overlying the anatomic sites of these valves.

The four principal auscultation sites are (1) at the apex of the heart, for the mitral valves (mitral area); (2) at the second left intercostal space close to the sternum for the pulmonary semilunar valves (pulmonary area); (3) at the second right intercostal space close to the sternum for the aortic valves (aortic area); and (4) at the junction of the fifth rib with the sternum on both the right and left sides for the tricuspid valve (tricuspid area)

Rhythm and Accentuation At each auscultation site both sounds of the heart are audible, and experience and training teach the art of distinguishing, at each site, the sound of autochthonous origin from the propagated sound Thus over the pulmonary and aortic sites the second sounds are autochthonous and the first sounds are propagated.

Identification of the Heart Sounds. Over a healthy heart the distinguishing of the first sound from the second sound is readily accomplished by the accentuation and by the length of the pause following each sound In disease, however, the heart beats may become very irregular or the rate greatly accelerated Both the long pause and the first sound become relatively shortened and the heart sounds are like those of a fetus, so that the ear may not be able to distinguish the first from the second sound In such a case the examiner may help himself by palpating (simultaneously with auscultation) the apex beat or the carotid pulse.

The loudness of the sounds of the heart may be less or greater than normal.

Enfeeblement of the First Sound. The first sound is enfeebled when something exists that hinders the transmission of the sound, such as obesity, pulmonary emphysema, large pleural or pericardial effusion, defective contraction of the ventricles or alterations of the atrioventricular valves A feeble contraction of the ventricle may occur in any of the conditions that give rise to myocardial insufficiency. When vegetations appear, as in acute endocarditis, on the borders of the valves, the first sound may be diminished or may even disappear

Accentuation of the First Sound The first sound may be exaggerated in intensity when the transmission of the sound is facilitated, as in emaciated patients, or when there are gas-containing cavities near the heart (pneumopericardium, dilated stomach) Abrupt ventricular contraction, such as often occurs in emotional excitement or on physical exercise, augments the first sound, and certain alterations in the atrioventricular valves, such as thickening or induration, may have the same effect The latter may explain the loud first sound sometimes heard in chronic endocarditis, for example mitral insufficiency, and in arteriosclerosis of a mitral cusp

A marked accentuation of the first sound at the apex often indicates the existence of mitral stenosis The abrupt first sound heard in this disease is believed to be due to the more powerful vibrations set up by the sudden tension of the stiffened valve cusps

Enfeeblement of the Second Sound. The second sound may be feebler than normal owing to faulty transmission to the stethoscope, as in obesity, pulmonary emphysema, and pericardial effusion, and owing to lowering of tension in the aorta or pulmonary artery, as in myocardial insufficiency, anemia, hypotension, and in general debility.

The lesion of mitral insufficiency tends to enfeeble the first sound When in the course of a mitral stenosis a mitral insufficiency develops, the first sound may become somewhat feebler.

Accentuation of the Second Sound. The second sound may be exaggerated (accentuated) whenever the arterial tension is increased. Thus, marked accentuation of the aortic second sound usually indicates hypertension in the aorta.

When in addition to accentuation of the aortic second sound there is alteration of the quality or timbre, there often are changes in the semilunar valves themselves, in which case the sound is loud and has a certain tympanitic or ringing quality.

When the accentuation of the second sound is maximal to the right of the sternum, it is certainly aortic in origin, but when it is maximal to the left of the sternum, it is usually pulmonary though it is sometimes due to a sound propagated from the aortic orifice.

The pulmonary second sound is accentuated normally during youth; otherwise it is evidence of abnormally increased pressure in the pulmonary artery and may be due to some obstruction to the flow of blood in the lungs, such as emphysema, fibroid phthisis, or pulmonary arteriosclerosis, or to faulty circulation in the left heart

Changes in the Number of the Heart Sounds. Instead of the first and second sounds of the heart, there may be heard, either in healthy or in diseased hearts, three or four or even more sounds. The additional sounds may be due (1) to failure of the components of the first or second sounds to fuse to a single sound, especially when there is a disturbance in the synchronism of events in the two ventricles, or (2) to the formation of new sounds

Splittings and Doublings of the Heart Sounds (¾ Rhythm) The first sound ... marked altera-

the fault in coincidence is greater. Similarly the second sound may be either split or doubled Every degree of transition from slight splitting to distinct doubling may be met with. These phenomena are frequently noted in health at different phases of respiration. The doublings are common too in disease conditions, and are then audible in all respiratory phases When the mitral valve is damaged, the second sound is often split at the base. A splitting of the second sound at the apex is common in mitral stenosis.

Triple or Gallop Rhythms (¾ Time). The normal rhythm of the heart is fairly well maintained in the splittings and doublings Sometimes the heart sounds, however, appear as groups of three sounds, of which the first and second and the second and third are separated by approximately equal intervals, while the last member of each group is separated from the first member of the next succeeding group by a somewhat longer pause, and for this reason it is fancied to resemble the sounds of the hoofs of a galloping horse (an awkward nag), three hoofs down followed by the fourth hoof (gallop rhythm)

The terms presystolic gallop and protodiastolic gallop are contradictory. These extra sounds are related to the complex of sounds constituting the first heart sound. They are neither diastolic nor systolic in time. Sometimes the extra sound precedes the first sound of the series (presystolic gallop), sometimes it follows (protodiastolic gallop). Gallop rhythms are usually most distinctly audible just medial from the apex of the heart, though the rhythm can usually be heard over the whole cardiac area.

The existence of gallop rhythm can be confirmed by palpation, inasmuch as the extra tone is accompanied by a *distinct shock palpable at the apex*. The tactile perception of the rhythm may be more definite than the acoustic perception

A gallop rhythm may be a normal phenomenon when third sound is audible.

It may be heard when a hypertrophied left ventricle is beginning to yield to the strain, and therefore its recognition may be more important for diagnosis and prognosis than that of a heart murmur.

HEART MURMURS. The heart sounds, normal or abnormal, and heart murmurs are noises, never pure tone.

The chief difference between the sounds in the normal and the abnormal heart and the heart murmurs lies in the duration, and in the termination, of the noises. The normal sounds are briefer, and they cease more quickly. Murmurs tend to be longer and to fade away gradually. These differences correspond to the origin of the sounds. The normal sounds arise from a single sudden disturbance of the equilibrium of the sound-producing body, whereas heart murmurs are due to a repeated disturbance.

In studying heart murmurs, attention is paid to (1) the time (or phase) in the cardiac revolution in which the murmur occurs, (2) the site at which the murmur is best heard and (3) the direction and propagation of the murmur. Less important features are (4) the intensity of the murmur, (5) its pitch and (6) its quality or timbre

Timing. The first determination to be made is the phase, or the phases, in the cardiac cycle in which the murmur is audible. All murmurs occurring between the beginning of the first sound of the heart and the end of the short pause marked by the beginning of the second sound are termed systolic murmurs All murmurs audible during the period extending from the moment at which the second sound begins to the end of the long pause marked by the beginning of the first sound are diastolic murmurs

The so-called presystolic murmur occurring just before the first sound of systole is in reality a diastolic murmur It is close to the normal systolic sound and far removed from the normal diastolic sound.

In fetal rhythms, when one of the heart sounds ceases to be audible, considerable difficulty may be experienced in timing a murmur. The best that can be done is to be guided by simultaneous auscultation and palpation of the apex beat or of the carotid pulse

In describing the position of a murmur, it is well to state where it is best heard and the direction of its conduction of propagation

Propagation As a rule, a murmur is best conducted in the direction of the flow of the current that produces it. It is desirable to ascertain not only the point at which a heart murmur is maximal but also the manner in which the murmur is propagated in one or more directions from this point. If, for example, a systolic murmur is produced by narrowing of the aortic valves (aortic stenosis), the murmur will be maximal at the auscultation site for that valve in the second intercostal space to the right of the sternum, and the murmur will be propagated upward toward the carotid and the subclavian arteries since this is the direction in which the blood flows from the narrowed spot at which the murmur arises.

If the aortic valves leak so that blood can pass back through them into the left ventricle during diastole (aortic regurgitation), the diastolic murmur will be propagated downward and to the left along the left margin of the sternum, corresponding to the direction of the regurgitant flow.

In narrowing of the mitral valve (mitral stenosis) the blood is forced through a narrow slit directly toward the apex of the heart, and during the period of the contraction of the atrium a systolic murmur in the region of the apex is heard. If the mitral valve leaks and blood regurgitates through it during contraction of the ventricles (mitral regurgitation), the murmur may be best propagated toward the apex of the heart, for instance in a direction opposite to the regurgitation. The murmur is sometimes best propagated toward the left atrium, and a systolic murmur may be audible either at the apex or in the pulmonary area.

When multiple heart murmurs coexist, a determination of the maximal and minimal points for each murmur and of the direction in which it is propagated is desirable.

If a murmur should be heard equally strongly in two areas, it is probable that an autochthonous murmur exists at each site, since a murmur propagated any distance is likely to be lessened in intensity.

In the presence of coexisting systolic and diastolic murmurs over the heart, the origin of the diastolic murmur is first located and analyzed, for diastolic murmurs are likely to be the most significant from the standpoint of diagnosis Subsequently the systolic murmurs may be analyzed for themselves

As a general rule, aortic murmurs are propagated toward the upper part of the body and mitral murmurs toward the lower.

Intensity Diastolic murmurs are usually less intense than systolic, though not always The two factors concerned in intensity are (1) the size of the opening and (2) the force, or velocity, of the flow. Care should be taken not to overestimate the importance of intensity for prognosis, for a very loud murmur may accompany a slight lesion, whereas a very soft murmur may coexist with a serious lesion of the heart With a given murmur, a patient's condition may be better when the murmur is intense than when it is feeble, since the intensity may vary with the force of the cardiac contraction

The intensity of a murmur increases and diminishes with the changes in blood pressure When a heart hypertrophies, the murmurs in it may become intensified, and when a heart weakens, the murmurs may grow feebler

The intensity of heart murmurs may also be influenced by posture. Most murmurs are more intense when the patient is in the recumbent position than when standing, the heart rate is less, and the ventricles contract more energetically.

The condition of the walls of a diseased orifice may affect the intensity of the murmur produced there Rigid, or calcified, valves may emit loud sounds, whereas soft, fresh thickenings of the valves may give rise to feeble murmurs

Quality According to the peculiar quality that heart murmurs manifest, they are designated as blowing, rasping, scratching, filing and musical, along with any other descriptive adjective the observer may desire to employ

Origin Under normal conditions the relations that exist among the cavities of the heart, the valvular orifices, the velocity of flow and the composition of the blood are such that no murmurs arise, but an abnormal condition of the orifices or a change in the velocity of flow or in the composition of the blood gives rise to murmurs

Significance A murmur audible over the heart may arise inside the heart (intracardiac murmur) or outside the heart (extracardiac or exocardial murmur). A murmur may be produced by organic disease of the heart valves (organic murmur), or it may be independent of such disease (functional heart murmur), or it may have its origin in conditions not due to disease of the heart muscle or its valves (accidental murmur), in which it may depend on changes in the physical state of the blood (anemic murmur) or on increased rapidity of flow (velocity murmurs in fevers) or on causes unknown

Organic Intracardiac Murmurs. Pathologic changes in the cardiac valves may lead to imperfect closure of the orifice, and this is designated valvular insufficiency A permanent narrowing of the orifice is known as valvular stenosis Murmurs due to insufficiency of a valve will be produced in those phases of the heart action during which the orifice is normally closed, whereas murmurs due to stenosis will arise when the orifice is open and the blood current is passing through it in the normal direction.

Functional Heart Murmurs Murmurs are frequently audible over the heart during life, though at necropsy no changes in the valves of the heart are demonstrable

Such murmurs, independent of anatomic lesions of the valves, are called functional murmurs. That a certain number of these are due to imperfect contraction of the muscle ring around the valve, leading to a relative insufficiency of the valvular closure, has been postulated Relative insufficiencies, if such exist, are common at the mitral and tricuspid orifices. They occur occasionally, but rarely, at the aortic orifice and perhaps also, though still more rarely, at the pulmonic orifice (Graham Steell murmur).

In all forms of anemia, especially in uncontrolled pernicious anemia, systolic murmurs may be heard over the whole heart; occasionally an anemic diastolic murmur is audible Perhaps some of the so-called accidental murmurs audible in cachexias may depend on the accompanying anemia.

In conditions in which the action of the heart is excited (fevers, neurasthenia, hyperthyroidism) systolic murmurs are often audible in the pulmonary region and over the left ventricle

A certain number of murmurs have their origin in the lungs during movements of the heart (cardiorespiratory murmurs)

The criterion for differential diagnosis between these less important murmurs and the more important murmurs due to organic disease of the valves or to relative insufficiency is not definite In general, the less important murmurs are systolic rather than diastolic. They are less precisely localizable than the organic murmurs. Many of them are heard in regions in which organic murmurs are rarely present

The less important murmurs are more variable in intensity than organic murmurs, especially under the influence of the respiratory movements and of change in posture Most important of all, they are not accompanied by those other changes in the heart and circulation that follow an organic disease of the valves.

Dorsal Auscultation According to Lian and Dang-van-Chung, diagnosis of certain cardiovascular disturbances cannot be established by auscultation of the anterior aspect of the thorax but may be elicited by auscultation of the back of the thorax This applies particularly to congenital stenosis of the aortic isthmus, in which a loud systolic murmur may be heard at the left omovertebral space. A systolic murmur can be heard along the left border of the vertebral column in the two inferior thirds of the left side of the thorax in cases of aneurysm of the descending aorta Dorsal auscultation may be an aid in the detection of continuous murmurs due to the compression of a branch of the pulmonary vein or to the presence of an intrapulmonary arteriovenous aneurysm An anterior mitral systolic murmur which is propagated to the back and is heard on dorsal auscultation is highly indicative of mitral insufficiency According to the site of its greatest intensity a systolic murmur at the base of the heart when propagated to the back and detected on dorsal auscultation may be of aid in the diagnosis and the localization of the causative lesion in the aorta (right supraspinous fossa) or in the pulmonary artery (left supraspinous fossa) The continuous murmur caused by the compression of the superior vena cava and that due to patent ductus arteriosus are propagated to the back only during systole Pericardiac friction sounds may be heard on dorsal auscultation in exceptional cases.

THE IMPORTANCE OF CARDIAC AUSCULTATION The importance of cardiac auscultation has been recently emphasized by Samuel A. Levine, who observes that if the competent examiner fails to hear any murmurs whatever, even with the patient turned to the left lateral and dorsal position or sitting upright, it can be safely assumed that subacute bacterial endocarditis or chronic rheumatic valvular heart disease is not present If a patient who has had rheumatic fever is examined one or more years afterward, and fever and murmurs are not observed, the heart sustained no important permanent damage. However, if in a patient who has had rheumatic fever, there is any kind of murmur, heart disease should be suspected If a diastolic murmur is present in any patient, the presence of organic valvular

disease must be suspected or at least cannot be dismissed, for auscultation is th only method of detecting early valvular heart disease. Likewise the detection c pericardial friction almost invariably means acute pericarditis and this may be firs demonstrated by auscultation.

In regard to particular valvular heart lesions, Levine calls attention to the fac that the presence of an *apical rumbling murmur*, diastolic or presystolic in time is diagnostic of mitral stenosis This murmur establishes the correct diagnosi even if it is faint or present only after effort or when the patient is lying on th left side A faint early diastolic murmur at the base of the heart is most significan in the diagnosis of early aortic insufficiency. In some instances auscultation is th only method which will aid in the diagnosis of either slight mitral stenosis o aortic insufficiency, for the roentgenograms and electrocardiograms may revea essentially normal conditions, and even symptoms of heart disease may be absen or equivocal

Emphasis in this discussion by Levine is in accord with that of other cardiologists that there *are many systolic murmurs, of which proper evaluation may be extremely difficult. It is well known that systolic murmurs may be heard in both valvular anc* nonvalvular disease of the heart and may be present in patients who are suffering from noncardiac disease or no disease at all. This does not detract from the value of auscultation In general a faint systolic murmur may be heard with or without heart disease but louder ones will seldom be present in normal persons and usually will indicate some form of heart disease

In a patient who has a severe epigastric pain of sudden onset in whom auscultation of the heart reveals a diastolic gallop, electrocardiographic studies usually will confirm the suspicion that the heart is the origin of the illness The detection of a snapping first sound while the heart rate is very rapid and grossly irregular in the absence of any murmurs is enough to arouse suspicion of the presence of mitral stenosis. Later, when the rate slows after digitalis therapy, the characteristic diastolic murmur may become audible A hyperactive first sound is present in thyrotoxicosis An exact doubling of the heart rate from 70 to 140 after brief effort arouses the suspicion of the presence of auricular flutter.

Many patients who display perfectly good or even loud first heart sounds are observed to have various forms of advanced cardiac disease, even with gross congestive failure. Others, on the contrary, who have faint and occasionally inaudible first sounds, are healthy

Levine has expressed the belief that in complete heart block, when the ventricles are beating very slowly and regularly and the auricles more rapidly, regularly and independently, the first sound varies greatly in intensity It is found to be loudest when P-R interval is exceedingly short and often the observer may be able to estimate the length of the P-R interval and to recognize conditions in which there is a short P-R interval, others with a prolonged P-R interval (first degree heart block) and those in which this interval is varying, such as second and third degree heart block In Levine's opinion, the detection of these changes in the intensity of the first sound is the only reliable bedside method of making these diagnoses If the heart rate is regular and the first sound decidedly decreased while the second sound is normal, the P-R interval will be at least at the upper limit of normal or delayed systole. Similarly, if the rate is regular and slow and the first sound changes in intensity with sudden loud explosive sounds, there is complete heart block with dissociation of the auricles and ventricles

Exocardial Murmurs. Abnormal sounds audible over the heart, synchronous with its action but arising *outside its cavities*, are (1) *pericardial friction* (see Pericarditis), (2) pleuropericardial friction, (3) cardiorespiratory murmurs, (4) precordial crackling characteristic of mediastinal emphysema (see Diseases of Mediastinum, Chapter 9) and (5) splashing sounds.

Pleuropericardial Friction Sounds A pulsatile friction sound, produced by rubbing of the outer surface of the pericardium against the pleura, may be synchronous not only with the heart's action but also with the respiratory movements. The portion of the sound due to the latter will cease when the breath is held.

Cardiorespiratory Murmurs These sounds arise in the lungs chiefly during the systoles accompanying inspiration. Occasionally diastolic sounds are produced and, sometimes, the sounds are audible during expiration also. The heart becomes smaller during systole and the ingress of air in the adjacent lung is increased, owing to greater negative pressure in the lung. The sounds may be blowing, like those of vesicular breathing, or crackles and rales may be produced. The systolic vesicular breathing may closely resemble a heart murmur These pulsatile pulmonary sounds usually cease, or are markedly modified, when the breath is held They are also much influenced by changes in posture.

When the lung is adherent in front of the vessels at the base of the heart, a diastolic murmur sometimes becomes audible, the diastolic retraction of the aorta causing a localized aspiration into the adjacent pulmonary alveoli.

Splashing Sounds. If the air and fluid occur together in the pericardial cavity, each beat of the heart may give rise to a metallic, ringing splash Similar sounds are sometimes heard when there is a pulmonary cavity near the heart, when a hydropneumothorax exists, or even when the stomach is much distended with fluid and gas

If sounds have an extrapericardial origin, they will disappear when the patient is sitting, to reappear when he lies down, but if they have an intrapericardial origin, the sound is heard in both positions

AUSCULTATION OF THE BLOOD VESSELS When one is listening over the blood vessels, care must be exercised not to exert pressure with the stethoscope, otherwise a narrowing of the vessel will be produced which will give rise to a murmur.

Auscultation of the Arteries The observer locates the vessel by palpation and sets the bell of the stethoscope lightly upon it. Normally two sounds are audible in the subclavian and the carotid arteries, the first just after the beginning of ventricular systole, the second just after the beginning of ventricular diastole. If the artery is pressed on now with the stethoscope, a ventriculosystolic stenosal murmur will become audible. No sounds are audible, normally, over the other arteries of the body

Systolic murmurs due to narrowing at the aortic orifice are often propagated into the carotid and the subclavian arteries When the aortic second sound is absent, as in some cases of aortic insufficiency, no arteriosystolic tones are heard in the great vessels.

When a Corrigan pulse exists, the pulse wave rising quickly and sinking again very rapidly, murmurs are often audible in the arteries of the neck and in the femoral and the brachial arteries The phenomenon is most often met with in aortic insufficiency but it may also be encountered in hyperthyroidism, in fever, and in nervous palpitation When a very loud sound is audible, it is spoken of as a pistol-shot sound

In aortic insufficiency, on listening over the femoral artery, two tones, quickly following one another, are sometimes to be heard (Traube's double tone) On slight pressure with the stethoscope these tones disappear, and first is heard a normal pressure murmur and, later, on stronger pressure, a second murmur (Duroziez's double murmur) Duroziez's double murmur is hard to differentiate from the normal pressure tone

Any compression of an artery may give rise to a stenosal murmur, for example, this fact is utilized in the auscultatory method of determining maximal and minimal blood pressure.

Auscultation of the Right Jugular Vein. The stethoscope is placed over the sternal attachment of the right sternocleidomastoid muscle, the patient sitting or standing with the head turned toward the left.

In the jugular vein certain sounds become audible under abnormal conditions, they include (1) the venous hum and (2) the venous tone.

In anemic patients, and occasionally in healthy persons, a continuous blowing, singing or humming murmur, with systolic accentuation heard over the jugular vein, is a venous hum Less continuous, more intermittent, venous murmurs are unimportant

Venous tone is occasionally audible, in the same situation, in tricuspid insufficiency; it is due to sudden tension of the dilated vein when the blood propelled by the contracting right ventricle rushes into it.

Movements of the Heart and Blood Vessels. The signs of the activity of the heart include the heart sounds (page 644), and certain movements of the heart and blood vessels that are accessible to clinical examination. These movements are visible and palpable as pulsations in the heart and its neighborhood and in the arteries and veins of the body. The movements can be most accurately analyzed by means of instruments of precision yielding graphic records.

With the hand most of the movements which can be seen can be felt, and a number of movements that cannot be seen are recognizable by *palpation*. Thus, for example, an apex beat that is invisible may sometimes be felt; various invisible shocks and thrills are palpable; and, in addition, details of the movements of the blood vessels that are not accessible to inspection can be made out on palpation

In practicing palpation, the palm of the hand (the tips of fingers for the pulse) is applied lightly and with varying degrees of pressure on the area to be examined. The region of the apex of the heart first, and successively the whole precordial area, the axillae, the vessels in the neck, the epigastric and hepatic regions and the more superficial vessels in various parts of the body, including, of course, the vessels of the feet, are palpated

Low-pitched murmurs are the ones that favor the formation of thrills, whereas those that yield rapid vibrations producing high-pitched murmurs may not give rise to palpable thrills This explains why a thrill may sometimes be felt when a murmur is not audible or is a very indistinct rumble and why the loudest and most distinct blowing murmurs may be unaccompanied by thrills. Palpation and auscultation here supplement one another advantageously in diagnosis

Abdominal Pulsations. Pulsation, due directly or indirectly to the heart, is present in the epigastric fossa, in the neighborhood of the xiphoid process between the two costal margins It may depend on (1) the abdominal aorta or (2) the right ventricle

The commonest aortic form is that met with in neurasthenics and emaciated dyspeptics with thin, loose abdominal walls, the so-called dynamic aorta This pulsation is slightly to the left of the middle line and extends for a variable distance downward, below the xiphoid process The pulsation is perpendicular from behind forward, has only a slight breath and is somewhat later than the apex beat. One tone, or a systolic murmur, may be audible on auscultation The pulsation is increased by anything that excites the heart's activity. In many cases in which this form of aortic pulsation is present, the aorta can be grasped in the palpating hand, which then becomes aware of marked lateral expansion with each pulsation In such cases, however, the aorta can be palpated lower down and the same condition found; there is never a localized expansile tumor such as is present in aneurysm of the abdominal aorta

Epigastric pulsations due to the right ventricle itself may be either systolic elevations or systolic retractions Systolic elevations are usually due to a lowered

and enlarged right ventricle (pulmonary emphysema, dilated right heart, right heart failure, cardioptosis).

Systolic retractions in the epigastrium, due to the right ventricle, are rather diffuse, wavelike movements depending on elevation of the diaphragm by the contracting right ventricle; they are of no clinical significance except when there is failure of the right side of the heart.

VISIBLE PULSATIONS Visible pulsation of the peripheral arteries occurs in aortic insufficiency For the characters of the arterial pulse, however, reliance is made on palpation.

Pulsations in the veins of the neck may be visible in health, though they are much more often seen in disease. A normal venous pulse when visible presents two waves recognizable by the eye, both diastolic. Palpation is of little value in the study of the venous pulse.

A visible capillary pulse is met with in conditions associated with hypertrophy of the left ventricle, especially in aortic insufficiency If a line is scratched with the fingernail on the forehead or on the skin of the trunk, or if light pressure is made on the end of the patient's fingernail in order to make a pale spot in the nail bed, the borders of which may be closely watched, alternately blush and pallor synchronous with the pulse are revealed if a capillary pulse exists A very good way to look for a capillary pulse is to press gently with a glass slide on the lips Sometimes, a blush of the cheek can be seen with each systole of the heart.

THE PULSE By pulse is meant the pressure wave of enlargement of the artery which occurs at each systole of the heart and which takes a perceptible time to travel from the heart to the periphery. Attention is paid to the following qualities: (1) the frequency, (2) the rhythm, (3) the volume, (4) the quickness or celerity, (5) the tension and (6) the equality on the two sides of the body

The thickness of the vessel, which is usually attended to at the same time, is not a pulse phenomenon, but has to do with the condition of the arterial wall itself.

Rate. This varies in healthy adults between 60 and 90 beats per minute; in children, 90 to 140, in old age, 70 to 90. The pulse is faster in women than in men On sitting or on lying, the pulse is slower than on standing or on exercising

Acceleration of the pulse rate is due to cardiac hurry or tachycardia It is met with normally on exertion, during emotion, pain, fever, and after taking food

In hyperthyroidism, and in some neurasthenic states, tachycardia is common A frequent pulse is often an important sign of cardiac weakness or collapse. In paroxysmal tachycardia, attacks of great frequency of rate having a sudden onset, and ceasing suddenly, are met with, alternating with periods of normal frequency. The attacks may last from a few minutes to several days, the pulse beats often numbering between 140 and 280 per minute

Slowing of the pulse rate is known as bradycardia It is met with in convalescence from many infectious diseases, especially typhoid fever, influenza and pneumonia, in disturbances of digestion, in conditions in which the vagus centers are stimulated (brain tumors, hydrocephalus, beginning meningitis), in icterus and in various diseases that affect the heart itself (aortic stenosis, coronary sclerosis, myocarditis). In Adams-Stokes syndrome, in which the stimulus from the sinus and auricles is prevented from reaching the ventricles, the latter contract in their own independent rhythm, in these cases the arterial pulse rate may fall below 30

Rhythm Normally the single pulse waves follow one another regularly, but in pathologic conditions the rhythm may become irregular The irregular pulse is due to cardiac arrhythmia Under this heading there are included (1) respiratory irregularities, (2) extrasystolic irregularities, (3) heart block, (4) perpetual arrhythmia and (5) the alternating pulse

Volume. What clinicians speak of as the volume of the pulse is dependent chiefly on the difference between the increase in pressure during ventricular systole and

the decrease in pressure during ventricular diastole. The size of the pulse waves depends chiefly on (1) the volume of the systolic output of the left ventricle and (2) the ease with which blood flows out of the arteries through the capillaries. The volume of the pulse is, therefore, the palpatory equivalent in the radial artery of what is known as the pulse pressure (difference between maximal systolic and minimal diastolic pressure).

If the pulse wave rises very quickly and falls rapidly, it is spoken of as a water-hammer pulse (Corrigan pulse).

Tension This is judged by the force required to obliterate the pulse when the fingers press on it Three fingers are placed on the radial artery, the most pressure is applied with the distal finger hard enough to prevent a recurrent pulse wave through the palmar arch, pressure is then made with the most proximal finger until the pulse ceases to be perceptible to the finger in the middle. If difficult to compress, the pulse is said to be of high tension, when easily compressible, it is of low tension

Equality. The commonest cause of differences in the pulse in the two radial arteries is the presence of an abnormally small radial artery on one side. This is a common anomaly in the arterial system of the forearm. As a result the pulses vary chiefly in absolute volume, they are equal in time. In aneurysm of the arch of the aorta, or of one of the arterial trunks supplying the arms, differences in the time as well as in the volume and tension of the two pulses are prominent

Changes in the Cardiac Rhythm. The clinical significance of changes in the cardiac rhythm, especially the cardiac arrhythmia, has been greatly clarified by the studies of Thomas Lewis and by the use of electrocardiograph Increase in the cardiac rhythm beyond the limits of the normal number of heart beats per minute is tachycardia Decrease in the cardiac rhythm below the limits of the normal number of heart beats per minute is bradycardia

The *tachycardias* with a *regular pulse* rhythm, as proved by the electrocardiogram, include sino-auricular tachycardia, paroxysmal auricular tachycardia, ventricular tachycardia and most instances of auricular flutter. Tachycardias with an *irregular pulse* rhythm include auricular fibrillation and sinus tachycardia with premature beats.

Bradycardias with *regular pulse* rhythm include sinus bradycardia, nodal rhythm, constant partial heart block and complete heart block. *Irregular bradycardias* include sino-auricular bradycardia with frequent premature beats and partial heart block with frequent dropped beats

Irregular rhythms with normal heart rate are found to include premature beats, auricular fibrillation with ventricular rate slowed by digitalis, sinus arrhythmia and partial heart block with dropped beats

In *sinus tachycardia* the cardiac impulse as recorded on the electrocardiograph arises normally in the sino-auricular node The heart rate is increased Since the heart rate of normal individuals varies greatly, it is well not to interpret an increased pulse rate as being abnormal until it is known whether the particular rate is abnormal for the patient in question. The origin of the activating impulse is revealed by the electrocardiograph. If the impulse arises in a ventricular focus, it causes ventricular premature beats. If the impulse arises above the bifurcation of the bundle of His, it causes supraventricular premature beats. In supraventricular premature beats the impulse arises in the auriculoventricular node and thus the beats are termed nodal premature beats. If the impulse arises elsewhere in the atria, there are auricular premature beats.

In tachycardias there may be no subjective symptoms, or there may be disagreeable palpitation, fatigue and breathlessness

Examination of the heart and pulse discloses a regular rhythm with a rate exceeding 90 to 100, but less than 160, per minute Differentiation from other tachycardias with regular rhythm may be surmised or made from the electrocardiogram.

In *sinus bradycardia* the cardiac impulse arises normally in the sino-auricular node as revealed by the electrocardiograph. Symptoms of sinus bradycardia are absent except in the extremes, when there is dizziness, faintness or syncope. Syncopal attacks if they occur may be due to cardiac asystole. Examination of the heart and pulse discloses a regular rhythm with slowing of the heart rate below 60 per minute.

In *sinus respiratory* or *juvenile arrhythmia* the cardiac impulse arises normally in the sino-auricular node as revealed by the electrocardiograph and the arrhythmia is characterized by alternating periods of slower and more rapid cardiac rates which are usually related to respiration. The heart rate increases with inspiration and diminishes with expiration

Sinus arrhythmia is recognized clinically by regular but more rapid heart beats during inspiration and slower beats during expiration The periodic variation in the rate is intensified by deep breathing and stopped by breath-holding or by exercise. A sinus arrhythmia is of no clinical importance

In *sinus arrest* (sino-auricular standstill or sinus pause) there is momentary failure of the sinus node to initiate an impulse. The failure is caused usually by digitalis or quinidine intoxication Clinically the rhythm is regular, but there is slowing of the pulse. An electrocardiogram is essential for diagnosis.

When heart beats are controlled by the *auriculoventricular node*, there is a shifting pacemaker Auriculoventricular rhythm occurs relatively infrequently. It is almost always a transient phenomenon alternating with sinus rhythm Clinical symptoms are uncommon and rarely distressing. Diagnosis requires electrocardiographic study

When there is shifting of the pacemaker, there may be *reciprocal beats,* that is, there is an auriculoventricular rhythm in which the ventricles contract before the atria The atrial activation is delayed long enough so that the ventricles can respond to the returning auricular (nodal) impulse This phenomenon is often induced by pressure on the carotid sinus or digitalis therapy Diagnosis is by electrocardiogram

In other instances of a shifting of the pacemaker there may be *auriculoventricular rhythm* and *auriculoventricular dissociation*. In auriculoventricular dissociation there are responses to different pacemakers The ventricular rate, controlled by the auriculoventricular node, may exceed that of the atria which are responding to a depressed sino-auricular node This type of auriculoventricular dissociation is usually the result of digitalis, or of infections such as rheumatic fever In this condition the dissociation results from complete auriculoventricular block The electrocardiogram is necessary for diagnosis

Premature beats or extrasystoles are cardiac contractions of ectopic origin which occur earlier than expected in the dominant or usual rhythm They are distinguished electrocardiographically by their point of origin, for instance auricular, auriculoventricular or nodal, and ventricular premature beats

When there is recurrently a normal beat followed by an extrasystole, the rhythm is coupling of beats (bigeminal pulse) Bigeminal pulse is induced by two beats in close proximity followed by a long compensatory pause. The commonest type of coupling is due to alternate extrasystoles and is caused by digitalis Coupling of beats may also result from partial auriculoventricular block, not the result of digitalis, in which every third beat (trigeminal pulse) is dropped and thus a 3 2 sino-auricular block exists If every fourth beat is blocked, there is a 4 3 sino-auricular block

The majority of patients who have premature beats do not have organic heart disease The presence of heart disease may increase the occurrence and frequency of premature beats. In those who have premature beats and do not have heart disease, emotional stress and conflict, mental or physical fatigue, irregular sleep and digestive disturbances, especially when these are combined with excessive smoking of tobacco or drinking of alcohol or coffee, increase the beats.

Premature beats occur at all ages. After the age of 50 years, the freque creases, and after 70 years, premature beats are very commonly present Al patient is aware of premature heart beats, there may be a sensation of stopj the heart, momentary faintness, or dizziness, and anxiety. The patient may d palpitation as an oppression, fluttering, thumping, skipped beats, or a sinkir ing Occasionally the discomfort is localized in or extends to the neck, wh patient experiences a sensation of fullness, tightness, pulsation or wave reacl the top of the head. This may be caused by the regurgitant stream from th atrium to the veins of the neck when the atrium contracts simultaneously w ventricle and the tricuspid valve is closed

During the occurrence of a series of extrasystoles there may be anxiety, sweating, nausea, weakness, dizziness, faintness and breathlessness

Premature beats often become annoying when the patient retires for the Conversely, exercise or anything which increases the heart rate eliminates tl mature beats

Premature beats are recognized by auscultation, occasionally by palpat the radial pulse. They may be absent at the time of physical or electrocardiog examination The electrocardiogram is essential for definite diagnosis and lo tion of premature beats.

A ... *cardia is manifested by a rapid but regular* rate ... rhyth ... node in its pathway.

The etiology of auricular paroxysmal tachycardia is obscure, but it seem organic heart disease is usually absent Auricular paroxysmal tachycardia occ any age, including infancy It is commonest between 20 and 40 years of age

Paroxysms of brief duration may be accompanied by mild palpitation symptoms at all. In the severer attack there is sudden onset with a thump c against the thoracic wall, followed by cutaneous palpitation, fluttering, raci pumping of the heart beat Often there are stenocardia and smothering sens: or epigastric distress

The psychic and reflex nervous manifestations may be profoundly express angor animi, syncope, anxiety, weakness, exhaustion, coldness, sweating, dizz and faintness Abdominal distention, gaseous eructations, salivation, naus vomiting, or polyuria may terminate the attack

It is remarkable how often heart rates of more than 200 per minute in p ... for hours or days without evidence of circu ... restored ... in ... there is organic disease it is ... 's fa

In the extreme and very exceptional instance the attack is prolong . In case there may be peripheral slowing of the circulation to the extent that throm and gangrene of an extremity occur. The attacks can terminate fatally, either signs of progressive failure or suddenly

On physical examination the only abnormality is a regular and constantly heart rate. In those who have organic disease there may be cardiac enlargemen murmurs.

In most cases auricular paroxysmal tachycardia is of no clinical import either from the viewpoint of producing disturbing symptoms or from that o noting the presence of organic heart disease, except in very rare instances in v the paroxysms recur frequently or are very prolonged.

The most useful therapeutic and often diagnostic procedure is to make pre over the right carotid sinus and, if this is ineffective, over the left carotid sinu

10 to 30 seconds. The carotid sinus may be located by feeling the strong carotid arterial pulsations at the bifurcation of the common carotid artery at the level of the upper border of the thyroid cartilage. The patient may be reclining or sitting with his head slightly forward and his neck relaxed. Pressure is best made with two or three fingers, compressing the artery and sinus posteriorly and medially against the vertebral spine. Occasionally a massaging motion is effective. Prolongation of the procedure is avoided because of the possible risk of syncope or cardiac standstill.

Auricular flutter is due to a mechanism related to auricular fibrillation or auricular tachycardia—a circus rhythm.

In auricular flutter the atria beat regularly at a rate of 250 to 350 per minute. As a rule, however, there are varying degrees of partial heart block (2:1, 3:2, 3:1, and others) Most commonly the ventricular rates vary between 100 and 150 per minute and there is a 2:1 block. With higher degrees of block, for example, 4:1, the ventricles may beat not only regularly but at normal rates, 70 to 80. In infants and rarely in adults there is a 1:1 ventricular auricular rate.

Auricular flutter does not necessarily indicate heart disease. However, it is often associated with mitral stenosis, and it may be present with hyperthyroidism, coronary arteriosclerotic disease and hypertensive heart disease. Auricular flutter may be associated with mediastinal disease, and may occur during surgical procedures in the thoracic cavity.

The symptoms of auricular flutter are sudden tachycardia, palpitation, fear of impending death, weakness, dizziness and syncope, and in some cases there are the symptoms and signs of congestive heart failure or shock

Auricular flutter is often more disturbing to the patient than auricular tachycardia because of its greater tendency to persist (days, weeks, months or years). Auricular flutter is likely to be followed by auricular fibrillation. In auricular flutter the pulse is regular.

Auscultation of the heart discloses apical rates which depend on the degree of heart block (2:1, 3:1 or 4:1). Sudden changes in rates indicate changes in the degree of the block Exercise may raise the ventricular rate and induce a constant degree of block and a regular heart beat.

The diagnosis is established by means of electrocardiographic studies

Auricular fibrillation is an irregular irregularity of the heart beat Like auricular flutter, it is regarded as a circus rhythm of an ectopic stimulus. In auricular fibrillation, however, the basic circuit is shorter and the frequency of circulation of the excitation wave is greater than in flutter.

Auricular fibrillation is associated with various degrees of auriculoventricular block. The auricular rhythm is irregular, the ventricular rhythm also in auricular fibrillation is irregular

Auricular fibrillation is commonly associated with severe organic heart disease. It may be present, however, in patients who have apparently otherwise normal hearts Auricular fibrillation occurs most commonly in rheumatic heart disease, coronary arteriosclerotic heart disease with heart failure, and hyperthyroidism Paroxysmal auricular fibrillation is particularly identified with hyperthyroidism, although it may occur in any type of heart disease, including congestive heart failure as well as subacute bacterial endocarditis It may occur in paroxysms in the first two weeks after an acute myocardial infarction, but in the latter condition it usually subsides spontaneously after several hours Most frequently auricular fibrillation is observed in patients more than 40 years old Women are more commonly affected in the younger age period, that is, in hyperthyroidism and mitral stenosis, men, in coronary artery disease and hence in the older age periods

Often the onset of permanent auricular fibrillation impairs the cardiac sufficiency to a degree that heart failure is chronic thereafter In any patient who has auricular

fibrillation, auricular thrombosis may occur. However, thrombus formation and subsequent infarctions are common in mitral stenosis, with or without auricular fibrillation

The heart rate and the pulse rate possess the quality of irregular irregularity In rapid ventricular rates the pulse rate is considerably less than the apical rate; this difference is termed a pulse deficit The pulse deficit results from failure of many of the weak ventricular beats to expel a sufficiently large column of blood to reach the radial artery The pulse deficit is increased by the inability of the counter to count weak pulse beats which are closely spaced.

In those individuals who have pulse deficits the diagnosis is made by this finding In all cases electrocardiographic studies are necessary for a diagnosis.

In an otherwise normal heart paroxysmal auricular fibrillation may be disturbing, but it is usually of no importance as regards the outlook for life or the development of heart disease

In the presence of organic heart disease a persistent auricular fibrillation is an unfavorable occurrence

Treatment for a *paroxysm* of auricular fibrillation is indicated only if the paroxysm is associated with distressing and prolonged palpitation, evidences of heart failure or of cerebral or peripheral ischemia.

In all other instances, if treatment for auricular fibrillation is necessary, it consists essentially of the use of digitalis or quinidine

Ventricular tachycardia is a rapid, regular rhythm initiated by stimuli arising in an ectopic focus in the ventricular conduction system The ventricular rate varies usually between 150 and 300 per minute. The atria may contract regularly and normally or may respond to retrograde conduction along the auriculoventricular bundle and node, while the ventricles respond to the ectopic ventricular stimulus.

Paroxysmal ventricular tachycardia is most often associated with recent myocardial infarction It may occur without myocardial infarction in association with hypertensive and arteriosclerotic heart disease after excessive exertion and after excessive administration of digitalis Occasionally, however, ventricular tachycardia is observed without evidence of organic heart disease.

The symptoms of ventricular tachycardia are identical with those of auricular paroxysmal tachycardia The diagnosis depends on the electrocardiographic studies

Ventricular tachycardia is a serious condition. Ventricular tachycardia with alternating direction of the ventricular complexes has been considered especially ominous and almost invariably fatal In some patients who do not have organic heart disease other than the arrhythmia, the prognosis is good. Administration of quinidine constitutes the treatment.

Ventricular fibrillation is observed as the result of myocardial infarction, general anesthesia, lightning shock, digitalis or quinidine, and as a terminal event in a variety of diseases. It is likely due to an inconstant circus rhythm

Ventricular fibrillation probably occurs more frequently in those who have not had heart disease than in those who have had it, for it is the terminating event in the lives of many individuals In heart disease it is the terminating event in angina pectoris, and in acute coronary occlusion and syphilitic aortitis The intravenous injection of drugs is often responsible for this serious cardiac arrhythmia. Faintness occurs when ventricular fibrillation lasts 3 seconds, syncope after 10 to 20 seconds, and convulsions, apnea and incontinence after 40 seconds.

Electrocardiographic studies are diagnostic if life is sufficiently prolonged to make the diagnosis If ventricular fibrillation is not immediately fatal, the patient may recover.

Heart block results from aberrations in the sino-auricular node, auriculoventricular node, bundle branch and short P-R interval with prolonged QRS complex.

Sino-auricular block may result from vagal stimulation, for instance a sensitive carotid sinus, tumors compressing the carotid sinus, vagal reflexes during anesthesia and surgical procedures, and cerebral lesions The usual cause, however, of sino-auricular block is poisoning by digitalis and occasionally quinidine

There are usually no clinical symptoms unless there are frequent and prolonged pauses However, in prolonged pauses there may be dizziness or faintness, and even attacks of the Adams-Stokes syndrome may occur Death resulting from cardiac standstill is not expected.

Sino-auricular block is distinguished by the electrocardiogram It is treated by stopping the administration of the heart medicine.

In *auriculoventricular block* there is a delay in transmission of the impulse through the auriculoventricular node and bundle, or an interruption of an occasional impulse or of all impulses in either the node or the bundle. Thus there are variations in degree of heart block from none at all to complete block.

Complete heart block is a common disorder of the heart beat, appearing in recurrent attacks, often leaving normal conduction between attacks The frequency of heart block is exceeded only by that of premature beats, auricular fibrillation and auricular paroxysmal tachycardia.

Complete heart block may be transient or permanent and it may represent a functional or an organic disturbance.

Coronary arteriosclerosis, rheumatic heart disease, syphilitic heart disease, neoplasms and congenital heart disease, and effects of the common drugs (digitalis, quinidine) used in therapy are the usual causes of heart block. Occasionally heart block is caused by acute infectious diseases, notably rheumatic fever and diphtheria, but at times by almost every other infection

In most instances of heart block associated with acute infections there is only a prolongation of the P-R interval In such cases the P-R interval may often be shortened to normal by the administration of atropine.

In the normal electrocardiogram the P-R interval varies between 0.12 and 0 2 second At slow cardiac rates (60 per minute or less) a P-R interval up to 0 21 or 0 22 may be normal In prolonged auriculoventricular conduction time the P-R interval exceeds 0 2 second In partial heart block there periodically is a dropped beat The P-R interval may increase progressively until a QRS is omitted, until the ventricles respond only to every second, third, or fourth beat, resulting in 2:1, 3·1, or 4.1 block

There are no symptoms The heart rate increases with exercise or excitement

In complete heart block there is the virtual regularity of atrial and ventricular activity with continual variation in the P-R interval The auricular rate is increased over the ventricular rate and both rhythms are essentially regular

In complete heart block the *Adams-Stokes syndrome* may occur The Adams-Stokes syndrome results from a prolonged systole of 5 to 10 seconds or more As the result the patient becomes pale and pulseless, and loses consciousness When the asystole lasts for 15 seconds or more, there is cyanosis, and respirations are deep and labored, or of the Cheyne-Stokes type There is a generalized convulsive seizure which lasts for a minute or longer Then the convulsive movements cease, and the pulse and respirations return to normal The color is restored Paroxysms longer than a minute may be fatal. Recovery may follow longer periods of asystole.

In partial or complete heart block the cardiac rate is slow, 50 to 40 per minute or less The lower rates prevail in complete heart block that is congenital, rheumatic, or due to digitalis

In complete heart block variations in the intensity of the first heart sound may

be heard. The auricular sound sometimes may be heard faintly between the regular heart sounds, or there may be reduplication of the first or second sound which may be thought to be auricular sounds.

The clinical significance, treatment, and the prognosis of heart block depend on the causative factor

In *bundle-branch block* there is a delay in or an obstruction to the conduction of impulses through one of the branches of the bundle of His, or there are obstructions in the Purkinje fibers.

Left and right bundle-branch blocks are identified. Left bundle-branch block occurs more frequently than right bundle-branch block.

The great majority of instances of bundle-branch block (left bundle branch) are due to coronary arteriosclerosis and associated hypertension The bundle branches are often damaged or blocked by cardiac infarction and degenerative changes secondary to myocardial ischemia

There are no symptoms of bundle-branch block. The definite diagnosis depends on the revelations of the electrocardiogram.

Blood Pressure. MEASUREMENT OF BLOOD PRESSURE Clinically the arterial pressure in the brachial artery is measured routinely. The maximal arterial blood pressure or systolic pressure is recorded as the highest point reached by the blood pressure in the artery during the ventricular systole. The minimal arterial blood pressure or diastolic pressure is recorded as the lowest point reached by the blood pressure within the artery during ventricular diastole

If the minimal blood pressure is substracted from the maximal blood pressure, the remainder is known as the pulse pressure. The term mean pressure is used to designate the average pressure *during a certain period*.

The principles underlying all the instruments for determination of blood pressure are the same The arterial pulse is obliterated by compression from without by means of a cuff, and the pressure necessary for compression is measured by some form of manometer. These instruments include the mercury manometers and aneroid manometers. The mercury manometers are preferable for office use. The aneroid manometer is convenient for bedside use, being small and easily portable. It may require, however, to be adjusted, at intervals, on comparison with a mercury manometer

ARTERIAL BLOOD PRESSURE. A cuff is applied over the brachial artery, and the pressure in it is raised until the radial pulse disappears The bell of the stethoscope is then placed over the artery close to the cuff, the position of the bell is the antecubital space It is customary to speak of five distinct phases as the sound varies during the fall of the pressure in the cuff.

First Phase When the pressure falls to the level of the maximal systolic pressure, an arterial tone is heard, not unlike the first sound of the heart It is due to the return of the pulse wave in the artery, the vibrations being supplemented by the resonance of the air within the cuff This is the maximal (systolic) pressure.

Second Phase As the pressure in the cuff falls further, the sound of the first phase is accompanied by a hissing murmur as the blood flows through the constriction into the wider artery below

Third Phase. As the minimal diastolic pressure is approached, the murmur of the second phase disappears, and a tone, usually much louder than that of the first phase, becomes audible.

Fourth Phase. At the end of the third phase, if the examiner listens attentively, the sound will be observed to become diminished suddenly and markedly and to assume a muffled character. The onset of this fourth phase formerly was considered to indicate the exact moment at which the pressure within the cuff corresponds to the minimal (diastolic) pressure in the brachial artery. Recently, however, a committee chosen by the American Heart Association has decided that in clinical practice the recorded diastolic pressure shall be the reading of the manometer at the end of the fif[illegible] hase.

Fifth Phase This is very short, at the end of it the sound disappears entirely This is now considered to be the diastolic pressure However, this arbitrary standard for diastolic pressure remains with the one limitation of all auscultatory methods. It is somewhat unsatisfactory when tones are audible in the peripheral arteries before the cuff is applied (for example, in aortic insufficiency).

CLINICAL ESTIMATION OF BLOOD PRESSURE The recorded level of blood pressure, in addition to individual fluctuation, is affected by numerous technical circumstances, such as the nature of the apparatus and whether the measurement is made by auscultation or by palpation In a study of the accuracy of blood pressure recordings, Ragan and Bordley compared auscultatory pressure measurements with intra-arterial pressure measurements 138 times in 51 adult subjects They found that the agreement between the auscultatory and intra-arterial measurements of systolic pressure was affected both by the size of the subject's arm and by the contour of the pulse wave They concluded, therefore, that the commonly employed clinical method of measuring blood pressure should not be considered a truly accurate procedure and that misinformation is particularly likely to be obtained in subjects who have unusually large or unusually small arms If the arm is small, the clinical estimate of the systolic pressure is likely to be too low, if the arm is large, the clinical estimate of both systolic and diastolic pressures is likely to be too high. The error in either direction may exceed 30 mm. of mercury. The error can be reduced in large-armed or fat-armed individuals if the width of the cuff is increased as it is in the cuffs for leg pressures In small-armed adult persons and in children the error can be reduced by the use of successively narrower cuffs

THE RANGE OF NORMAL BLOOD PRESSURE Master and associates record that the normal range of systolic blood pressure in men starts at the age of 16 years with 105 to 135 mm of mercury, and at ages 60 to 64 years reaches 115 to 170. In women it starts at a slightly lower level, at 16 years of age the normal range is 100 to 130 mm of mercury At ages 60 to 64 years the range is 115 to 175 This is slightly higher than in men

In men at ages 16 to 18 years the lower limit of hypertension is 145 mm. of mercury systolic; at 19 years, 150 mm., and at 30 to 34 years, 155 mm It then increases about 5 mm every five years At ages 60 to 64 years, 190 mm is the lower limit In women the lower limit of hypertension is 140 mm. of mercury systolic up to age 30 years Thereafter it increases 5 or 10 mm for every five years, and by age 45 years it is actually higher than in men The hypertensive limit remains higher than among men up to ages 60 to 64 years, when it may be taken as the same in the two sexes

The range of normal diastolic pressure begins at 60 to 86 mm of mercury at age 16 years in men and at 65 to 85 mm in women The change with age is gradual. By ages 40 to 44 years the level is 70 to 94 mm for men, after age 40 years the lower limit of normal remains the same, but the upper limit of normal gradually increases to 100 mm at ages 60 to 64 years In women the normal range at 40 to 44 years is 65 to 92 mm. and at ages 50 to 54 years rises to 70 to 100 mm ; it remains at this level to 60 to 64 years of age

Mean blood pressure readings, both systolic and diastolic, increase with age in both sexes Average systolic readings for men show a fairly smooth progression up to the age of 50 years, after that age the increase accelerates For women the increase in the averages by age is somewhat less smooth or continuous than it is for men, but among them, too, it is accelerated after the age of 50 years. Beginning with age of 20 years the upward progression in diastolic pressure with age is fairly steady for both sexes, systematic acceleration of the average is not found over any broad age period

Among boys between the ages of 16 and 19 years, an upward trend is observed in the averages for both systolic and diastolic pressures. Among girls, on the other

hand, values for both systolic and diastolic pressure are practically identical between the ages of 16 and 18 years and remain unchanged through the age period 19 to 24 years Explanation of this difference may lie in the fact that boys mature between the ages of 16 and 19 years, they become heavier and are much more active than are girls at these ages. Girls mature earlier. It has been long recognized that a rapid rise in blood pressure occurs during puberty and adolescence.

No clear-cut relationship between height and blood pressure has been established

Weight is an important and consistent factor in blood pressure changes. With increase in weight there is progressive increase in the averages in systolic and diastolic blood pressure, regardless of age or sex.

The difference in the mean systolic blood pressure of underweight and overweight groups at each extreme exceeds 10 mm of mercury in some instances; the difference in diastolic pressure is almost as great. Among women, particularly after the age of 40 years, the differences between the weight groups at either extreme with respect to the mean pressures, both systolic and diastolic, are even greater than are those among men Absolute and relative variations in blood pressures, as measured by the standard deviation and the coefficient of variation, also tend to increase with weight, particularly after the age of 40 years. In general, the greatest contrast in the mean pressure is found at the older ages and among women.

Blood Pressure Variations in the Two Arms In 1,388 blood pressure readings Rueger found the blood pressure to be the highest in the right arm in 992 readings, as compared to 274 in the left arm, and to be equal in both arms in only 122 readings. The systolic variation in the two arms was 10 or more points in 694 readings, and zero to 10 points also in 694 readings, out of the total of 1,388 tabulations The diastolic variation in the two arms was much less marked, with 920 readings showing less than 10 points difference, as compared to 468 readings showing a difference of 10 or more points

Casual and Basal Blood Pressures. Smirk defines casual blood pressure as the sum of the basal blood pressure and the supplemental pressure; this last represents the degree of blood pressure elevation above the basal level due to whatever degree of physical, emotional and suprabasal metabolic activity is present at the time of blood pressure measurement The basal pressure is the pressure measured at a time when physical, emotional and metabolic activity are reduced to a physiologic minimum Failure to obtain the true basal reading will not always be apparent to the observer, especially when the failure is due to emotional reasons Both normal and hypertensive subjects with a high basal pressure have a greater statistical expectation of having a high casual pressure than do those whose basal pressure is low. Likewise those with high supplemental pressures have a greater statistical expectation of a high casual pressure than do those whose supplemental pressure is low. In comparing one individual with another, the basal and supplemental pressures [illegible] are independent variables in the sense that the level of the basal [illegible]

[illegible] with the casual readings The fact that, when comparing one [illegible] within a comparable physiologic group, the casual blood pressure is to be regarded [illegible] of two independent variables has statistical implications. The supple- [illegible] among

Low Blood Pressure [illegible]

[illegible] to [illegible] m- [illegible] ilts [illegible] to develop [illegible] not neces- Poor vasomotor control and systolic blood pressure [illegible] sarily occur together The symptoms of persistent fatigue, dizziness and fainting

attacks are not due to persistent hypotension, being frequently found in association with normal or elevated blood pressure. These symptoms are frequently due to psychoneurosis.

It is notable in psychoneurotic patients who have blood pressure of 90 to 110 mm. that, at such times as the anxiety or other underlying emotional disturbance is less evident, not only are the general symptoms relieved but the blood pressure reading may be somewhat higher. Conversely, when the emotional disturbance again becomes prominent, the blood pressure may gradually fall to the lower levels.

Postural or orthostatic hypotension is characterized by the occurrence of faintness or loss of consciousness on rising from the recumbent to the erect posture In this disorder the blood pressure may fall sharply from normal or elevated levels in the recumbent position to pressures of the order of 40 to 50 mm systolic and 25 to 40 mm diastolic in the erect position with loss of consciousness. It is usually considered that postural hypotension is due to a failure of splanchnic vasoconstriction to offset the gravitational effects of the assumption of the erect posture.

Orthostatic Tachycardia and Orthostatic Hypotension. MacLean, Allen and Magath have divided orthostatic tachycardia and orthostatic hypotension into two groups: (1) inconsistent orthostatic failure of venous return and (2) consistent orthostatic failure of venous return

Inconsistent orthostatic failure of venous return is manifested by orthostatic weakness, faintness and occasional syncope associated with orthostatic hypotension or tachycardia, and an abnormal Flack reaction. The Flack reaction is characterized by increased intrathoracic pressure, the venous return fails to the extent that there are a marked decrease of the filling of the heart, decreased cardiac output and subsequent failure of the peripheral pulse. Both signs and symptoms disappear in the recumbent position Hypotension, if present, is associated usually with compensatory tachycardia There may be only tachycardia in the erect posture associated with occasional drops of blood pressure or diminished pulse pressure Both signs and symptoms are usually much worse in the morning after the patient first gets out of bed and quickly improve after the subject continues to maintain the erect state At times during the day an abnormal Flack reaction may be the only indication that the patient has a potential defect of venous return

Usually no objective evidence of an organic dysfunction of the autonomic nervous system can be demonstrated. The circulatory failure encountered in this inconsistent group appears to be associated with undue shifts of blood volumes and extracellular fluid, gravitating to the lower extremities The increased heart rates, low blood pressures and abnormal Flack reactions can be abolished by the assumption of the recumbent position or by the application of tourniquets around the thighs It has been the experience of these writers that the loss of volume of circulating blood through abdominal pooling appears to be a minor and relatively unimportant factor as compared with the loss related to the lower extremities

A normal man may exhibit at times the signs and symptoms of failure of venous return The margin between adequacy and incompetence is so narrow that when a man stands erect without moving he may be the subject of circulatory collapse Such failure may be precipitated by a variety of factors: exposure to heat, loss of blood, poor tone of striated muscle, psychic trauma or the maintenance of a recumbent state for overlong periods.

It is common to witness rapid heart rates and low blood pressures of patients who are allowed to stand for the first time after protracted rest in bed This postural instability is functional, in that it is reversible. If such a patient continues to stand erect for longer and longer periods each day, vascular stability is regained. The normal man can stand erect motionless for about one half hour (see Posture, Chapter 6)

Orthostatic hypotensive tendencies and orthostatic tachycardia are observed

commonly during gestation. Psychic syncope (fainting) seems to be largely postural and the cerebral ischemia can be prevented by the recumbent state. Some patients have constitutional defects of venous return which may be termed neurocirculatory asthenia. Occasionally the signs and symptoms of this disorder are orthostatic in origin and are characteristic of orthostatic failure of return of adequate amounts of venous blood to the heart

Caloric and rotational stimulation of the vestibules of normal man, varieties of seasickness and airsickness the symptoms of which are postural, undue exposure to heat, abnormal loss of body fluid and primary shock with its nervous basis of pain and psychic factors, all may demonstrate defects of venous return of varying degree which frequently play major roles in the total functional disability In these conditions the assumption of the erect posture may precipitate failure of venous return which is masked by the recumbent state

The pressure of hypertension is compatible with abnormalities of venous return Occasionally large drops in blood pressure of more than 100 mm. of mercury are observed when a patient who has hypertension first stands erect after a period of rest in bed Such changes of blood pressure are as a rule transient, lasting only a few seconds, but during this period the Flack reaction may be markedly positive, returning to normal when previous levels of blood pressure are established

Consistent orthostatic failure of venous return is manifested by severe orthostatic hypotension Objective evidences of disorders of the autonomic nervous system are common loss of sweating over large areas of the body surface associated with intolerance to heat, frequent absence of compensatory reflex tachycardia, and impotence Symptoms related to the deficit of venous return result from the erect posture or from application of a tourniquet to the femoral arteries of the legs. The Flack reaction is invariably positive, and frequently a deep inspiration will cause the peripheral pulse to disappear The signs and symptoms show classic exacerbation in the morning, which is related to rest in bed. Remissions are rare according to MacLean, Allen and Magath

Hypertension (Hyperpiesis) The term hypertension refers to a state of elevated blood pressure, both systolic and diastolic but frequently with only significant systolic increases, in a patient who does or does not have obvious or determinable organic changes in the tissues The condition may be attended with associated symptoms or may be asymptomatic If symptoms are present they may be associated with the primary disease—for instance, a glomerulonephritis—and not due to the hypertension

INCIDENCE. The frequency of hypertension increases steadily with age About one fifth of men between the ages of 20 and 29 years have readings of 140 mm systolic and 90 mm. diastolic or higher The greater degrees of hypertension are relatively infrequent at these ages, readings of 150 mm systolic and 100 mm. diastolic or more occur in only 1 of every 20 cases.

Hypertension of at least mild degree is common in middle-aged and old persons Blood pressures of 140 mm systolic and 90 mm. diastolic or higher are present in about 40 per cent of both men and women at ages 45 to 49 years, and in 60 per cent at ages 60 to 64 years Readings of 150 mm systolic and 100 mm diastolic or higher are found in nearly 20 per cent of persons by the age of 45 years Thereafter the incidence rises steadily to more than 35 per cent in both sexes between the ages of 60 and 64 years Whatever definition of hypertension is used, the condition is found more frequently in men than in women up to the age of 45 years. After that age the incidence is generally higher in women

Transient Hypertension. Levy, Hillman, Stroud and White made an analysis of the medical records of 22,741 officers of the United States Army in order to appraise the significance of *transient hypertension* Blood pressure readings higher than 150 mm. of mercury systolic or 90 diastolic were considered abnormally high

The length of the observation period was from 1 year to more than 25 years; 84 per cent were under observation from 5 to 19 years and 38 per cent from 15 to 19 years In 1,437 instances the duration of the observation period was 20 years or more

The frequency with which transient hypertension was first noted increased with age. The curve of increase was smooth, beginning with 5 9 per cent in the age group 25 to 29 years and reaching a plateau of 18.6 per cent at 50 to 54 years

At all ages, sustained hypertension developed more frequently in those with previous transient hypertension than in those who never showed an elevation of blood pressure. In both groups the rate increased with advancing years.

The rate for disability retirement of an officer who had cardiovascular-renal disease was consistently higher among those with transient hypertension than in those without, at all ages from 35 to 60 years

The death rate with cardiovascular-renal diseases was also higher in those with transient hypertension; the figures rose in the older age groups.

Hypertension and Endocrine Disorders. Hypertension occurs as a symptom of *endocrine disease,* and presumably results from hyperfunction of the thyroid and pituitary glands and from tumors of the medulla (paroxysmal hypertension) or cortex (Cushing's syndrome) of the suprarenal glands. In hyperthyroidism there is frequently a rise in systolic pressure and pulse pressure which is thought to be due to the increased general metabolism In cases of hyperfunctioning tumors of the suprarenal medulla, sometimes termed paragangliomas, the elevation of blood pressure usually, but not always, occurs in paroxysms There is evidence that the sudden, marked rises in blood pressure are due to the release of epinephrine or closely allied norepinephrine from the tumor.

Hypertension and Toxemia of Pregnancy. In the toxemia of pregnancy (eclampsia) hypertension is a prominent feature A similar type of hypertension is present in a condition which Keith and Wagener have designated as acute vasospastic disease with hypertension

A primary glomerulonephritis or an essential hypertension may exist before the onset of pregnancy and may undergo exacerbation in the course of the pregnancy with resultant toxemic manifestation, and these patients are best cared for if the primary renal or the primary vascular disease is recognized to exist along with the toxemia The patients in whom elevation of blood pressure occurs rapidly for the first time during pregnancy have a primary toxemia incident to pregnancy

Hofbauer has suggested that there may be a disturbed balance in certain hormonal regulatory mechanisms and homeostatic adjustments of normal gestation The various factors involved in the imbalance are to be seen in the hyperactivity of the pituitary, the adrenal cortex and the accessory medulla-like formation occurring in the cervical ganglia during gestation He has called attention particularly to the pronounced secretory

of the adrenal medulla The structure appears to act during the gestation as an accessory adrenal-medullary tissue functionally interrelated with the hypophysis, the adrenals, the ovaries and the placenta The histochemical appearance, in the pregnant state, of these pheochromocytes points to the increased formation of epinephrine, norepinephrine or allied substances The enhanced chromaffin activity of these ganglia has a stimulating effect on the anterior pituitary-adrenocortical system Certain physical factors in the second half of the gestation or during labor act mechanically to increase the release of epinephrine secreted by these cells into the circulation. In preeclampsia, Hofbauer points out, pronounced eosinopenia, sodium and chloride retention, increased urinary 17-ketosteroids and uric acid excretion afford sensitive indicators of anterior pituitary-adrenocortical stimulation, with the activation of secretion of pituitary adrenocorticotropic hormone most likely due to epinephrine

Hypertension and Arterial Degeneration. Atherosclerotic degenerative changes of both the larger and smaller arteries may cause an elevation of the systolic blood pressure but there is no increase in the diastolic blood pressure in the former.

Hypertension and Increased Intracranial Pressure. Increased intracranial pressure may cause a rise in systolic blood pressure (160-170 mm. Hg) but since such a mechanism is present for only a short time hypertension seems unlikely

Hypertension and Acute Vasospastic Disease. Wagener observed and described visible vasospastic changes in the retinal arterioles in those who have eclampsia He and others have observed the same condition of the retinal arterioles in men and in nonpregnant women. These patients have some of the symptoms of eclampsia. They have an acute onset of symptoms with a rapidly increasing blood pressure from its normal or elevated state prior to symptoms. These patients differ from those who have acute glomerulonephritis in that the evidence of renal damage is minimal or absent

Hypertension and Renal Disease. Patients who have acute glomerulonephritis often have hypertension which begins early in the disease This hypertension may persist or it may disappear when the glomerulonephritis heals. During this early period of hypertension and edema Keith observed that the fundi usually appear to be normal In an occasional instance, however, slight edema may be present about the disk margins and there may be present a few hemorrhages. These mild retinal changes and hypertension may be secondary to the general toxemia which caused the nephritis, including the fever

In those who have more severe acute nephritis, improvement of the hypertension, if present, and general improvement, as indicated by the disappearance of edema, come slowly. In these patients there usually develop chronic glomerulonephritis attended by a retinitis Some of them will have hypertension and some will not The retinitis develops as a result of edema, anemia and angiospasm. The patients who have both persistent moderate hypertension and generalized edema may have edema in the retina without fully developed retinitis.

In those who have chronic glomerulonephritis with a minimal increase in blood pressure or perhaps no hypertension and in whom there is anemia of severe degree, hemorrhages and cotton-wool exudates may appear in the retina without angiospastic accompaniments Such a retinitis cannot be distinguished in general from that seen in anemia from any other cause However, if the blood pressure is due to chronic nephritis, the presence of persistent narrowing of the retinal arterioles may help to distinguish the retinitis from that which occurs in primary anemias

Angiospastic retinitis characterized by edema of the disks, diffuse edema of the retina, exudates of a cotton-wool appearance, hemorrhages, star-shaped macular lesions and visible sclerotic changes in the arterioles may be present in patients who have chronic glomerulonephritis with complicating or associated diffuse arteriolar disease and hypertension These retinal findings indicate that a diffuse arteriolar disease has preceded the onset of glomerulonephritis

These angiospastic and sclerotic lesions in the retinal arterioles indicate that thenceforward the vascular manifestations, including the hypertension, will assume the dominant role in the progress of the disease.

Essential Hypertension. The cause of essential hypertension has not been assigned. The consensus is that abnormal physiologic processes which may give rise to hypertension comprise four factors: (1) increased cardiac output, (2) increased viscosity of the blood, (3) increased total blood volume and (4) increased resistance in the peripheral circulation. Increased cardiac output may be responsible for the hypertension found in some cases of aortic insufficiency and in patients with arteriovenous fistula However, in most instances of essential hypertension the cardiac output is normal. The viscosity and the total volume of the blood are in-

creased in polycythemia vera, whereas the blood pressure is normal or only slightly increased.

An increased *peripheral resistance,* that is, a resistance in the arterioles or capillaries, seems to be a prime factor in the production of the measurable arterial hypertension. This contention is based on histologic examination which reveals changes in the medial walls of peripheral arterioles throughout the body These changes consist of medial thickening which reduces the size of the lumina of the vessels A reduction in size of the lumina of these small vessels could give an increased resistance to the blood flow. As soon as the postulation is made that there are present increased peripheral resistance and arteriolar changes sufficient to cause an increase in blood pressure, there is no way to answer which came first, the peripheral resistance or the arteriolar changes

Goldblatt's experiments on the production of renal ischemia in animals have revived interest in the old question of the relation of renal disease to diffuse arteriolar disease and hypertension. The observation that hypertension will still develop in the ischemic kidney after the destruction of the nerve supply of the kidney indicates that there may be present an active hormone having its origin in the kidney and set free into the general circulation and that it is this substance which causes hypertension The nature of such a circulative substance and its mode of action are unknown. Prior to Goldblatt's experiments, Tigerstedt and Bergman demonstrated that a simple saline extract of the fresh renal cortex of normal rabbits contained a pressor substance which they called renin. This substance was not obtained from any tissues of the experimental animals other than renal tissues The site of action of renin appears to be in the peripheral arterioles

hypertension In the early period of essential hypertension in man there is no renal insufficiency.

Weitz observed the evidence of heredity in hypertension by measuring the blood pressure of brothers and sisters of hypertensive persons and found that the incidence of elevated blood pressure was significantly greater among siblings of persons with hypertension than among siblings of persons without hypertension. Ayman studied the blood pressure of every member of a family for three generations, totaling 32 members more than 13 years of age One hundred per cent of the first generation, 80 per cent of the second and 25 per cent of the third had elevated levels of the blood pressure on two or more readings Ayman in a later article reported on a direct study of the blood pressure, height and weight of 1,524 members of 277 families Elevated systolic and diastolic blood pressure readings occurred in 148 of 780 members of the second generation aged from 14 to 39 years These 148 subjects had the same average age and sex incidence as the entire group of 780 children, but they were 14⅓ pounds (6 5 kg) above the average weight compared to 4½ pounds (2 kg) above the average weight for the remainder of the group In families whose parents had absolutely normal blood pressures the incidence of elevated blood pressure in the children was only 3.1 per cent In families in which one parent had arteriolar hypertension the incidence of elevated readings in the children rose to 28.3 per cent In the families in which both parents had arteriolar hypertension the incidence of elevated readings in the children reached the level of 45 5 per cent Of 70 brothers and sisters of parents whose blood pressure was normal, 37 3 per cent had elevated blood pressure readings, whereas of 86 brothers and sisters of pa[illegible]

pressure rea

in the childr

as compared with similar relatives of subjects with normal blood pressure, offers strong evidence for the existence of a hereditary factor in the etiology of hypertension.

Faulty diets have been associated with, and assigned as a cause for, hypertension in some patients The responsible factors in or absent from the diet have not been determined

The group predisposed toward hypertension on a hereditary basis must frequently acquire faulty dietary habits, as habits of food selection are handed down through families with little change from one generation to the next The effect of diet and overweight is also well demonstrated by the benefit incident to correction of these factors in patients in whom hypertension has developed

Increased blood pressure is produced by *anger and fear*. Stimulation of the sympathetic nervous system in anger and fear by an increased amount of norepinephrine and epinephrine in the blood stream causes rise in blood pressure The repression of chronic fear or chronic rage according to the psychiatrist eventually manifests itself in the circulatory system by the production of a continuous state of increased tension through the mechanism of sympathetic nerves, and norepinephrine and epinephrine-induced generalized vasoconstriction

Long-continued increased tension eventually produces degenerative changes in the intima and thickening of the walls of the arterioles Although these changes frequently occur as one of the degenerative changes of increased age, they are apparently greatly speeded by hypertensive states Changes are generalized and include the afferent renal vessels.

It has been suggested that hypertension is due to abnormal development of arteriovenous fistulas such as normally exist in the tips of the fingers and toes and in certain parts of the kidneys There is little evidence to support this hypothesis.

Hines and Brown, interested in the vasomotor factors in hypertension, devised a standard test for measuring the maximal vasomotor response when the hand and arm were immersed in cold water Individuals who have essential hypertension show a much greater increase in pressures with the cold water test than those who do not have essential hypertension Among patients who had early or "preorganic" hypertension, the average increase of blood pressure was 34 mm. of mercury systolic and 25 mm diastolic Among the patients who had an "organic" stage of essential hypertension, the average increase of blood pressure was 47 mm of mercury systolic and 34 mm diastolic

As a result of a study of 190 members of 15 family groups, 6 without and 9 with definite evidence or history of hypertension, Hines and Brown expressed the opinion that the vasomotor reaction to cold follows an inherited pattern and that the excessive or hypertensive type of reaction occurs in the families in which there is a hypertensive diathesis. They were led to believe that "the abnormality of essential hypertension is an excessive response in the blood pressure to intrinsic and extrinsic stimulation. This hyperreactive vasomotor mechanism may be an important factor in the production of arteriolar hypertrophy and in the subsequent development of the organic stages of the disease."

Hines and Brown found that the systolic form of hypertension seen in cases of senile arteriosclerosis and in cases of glomerulonephritis gave definitely less response to the cold pressor test than did the pre-existent and existent stages of essential hypertension

For a long time comments have been made in regard to the temperament which was apparent early in the life of hypertensive patients. These children are tense and more conscientious than the average child of their age. On examination of such a child there is present evidence indicating vasomotor weakness such as frequent epistaxis; excessive menstruation, cold, sweaty and cyanotic hands, flushing; blinking of the eyes and other evidences of a high-strung temperament.

PATHOLOGY Barker has summarized the pathologic changes in hypertension as consisting primarily of the development of a spastic thickening of the walls of the arterioles throughout the body which gradually becomes organic The secondary manifestations are myocardial weakness and failure as the result of increased myocardial strain, and the premature development of degenerative changes in the large arteries, also as the result of strain The degenerative changes in the larger arteries occasionally result in rupture, more commonly in thrombosis, and either of these events may be serious or fatal if the vascular accident occurs in a vital organ such as the heart or brain Serious lesions of the kidneys may occur as the results of chronic ischemia in hypertensive patients. When death occurs, it is most commonly the result of myocardial failure, second most commonly the result of cerebral vascular accidents and third most commonly the result of renal insufficiency.

CLASSIFICATION OF ESSENTIAL HYPERTENSION. The most widely known classification of essential hypertension is Volhard's red and pale hypertension Keith and Wagener admit the merits of Volhard's basic conception of these two conditions, but they are convinced that it is more appropriate to classify hypertension on the evidence of the differences in the arteriolar changes. In support of the soundness of their classification, which is based on changes in the retinas, they took biopsy specimens from striated muscle and found a close correlation between arteriolar changes in the muscle and those revealed on ophthalmoscopic examination Muscles were selected for the purposes of biopsy because this tissue represents one of the large bulky systems of the body.

Their histologic study of biopsied muscle disclosed that in some cases the arterioles appeared to be normal, whereas, in many others the walls of the arterioles were thickened, the ratio of the diameter of the lumen to the thickness of the wall was definitely decreased In many instances this change was uniform for all the arterioles seen In some it was confined to the smallest arterioles, and in others there were marked variations and localized changes only Other changes consisted of increased prominence and tortuosity of the arterioles and an increase in the number and size of medial and intimal nuclei Occasionally there were organized thrombi, extensive intimal proliferation, complete occlusion of the lumen by simple hypertrophy of the media, and perivascular collections of lymphocytes and fibroblasts Medial necrosis was found in the arterioles of voluntary muscle as well as in those of the kidneys and other organs in malignant hypertension. None of these changes were found in the histologic sections of muscles of persons with normal blood pressure. Similar findings to those found in the arterioles of striated muscle were demonstrated in the arterioles of the retina

Keith and Wagener's classification of essential hypertension is based on the foregoing studies which emphasize the widespread dissemination of the arteriolar

sion the patient is assigned The division of hypertension into four groups by these observers is based on the following criteria.

Diffuse Arteriolar Disease with Hypertension, Group 1. These patients are usually between 20 and 55 years of age Members of this group constitute the great majority of those who have hypertension, and they often have good health for years.

The evidence of the hypertension often is first found at the time of routine examination Prior to such an examination there have been no symptoms There are no symptoms in the stoic individuals after they know the blood pressure is increased It is different in the psychoneurotic individuals, who often become hypertensive hypochondriacs.

On examination there may or may not be obesity. The blood pressure is 150 to 175 mm. of mercury systolic, 90 to 95 mm of mercury diastolic. Often the diastolic

pressure is normal The heart is not enlarged or seemingly abnormal in any way. When the radial artery is made pulseless at the wrist by compression at the elbow, the pulseless artery may or may not be palpated. If it should be palpable, it imparts the sensation of a soft, collapsible tube to the palpating finger.

Twenty-four-hour studies of blood pressure demonstrate the decidedly beneficial effect of rest on the hypertension. During rest and sleep the blood pressure is often within normal limits and the retinal changes are usually minimal and consist of mild narrowing or mild sclerosis of the arterioles. Spasm of the arterioles is not present

The changes in the arterioles of the muscles likewise are minimal. Examination of the urine reveals no abnormality, or at most the urine contains albumin grade 1 on a basis of 1 to 4, in which 1 indicates the least amount of albumin and 4 the greatest amount More than albumin grade 1 arouses the suspicion of a previous nephritis The urinary sediment is negative

Diffuse Arteriolar Disease with Hypertension, Group 2 These patients, like those of group 1, vary in age from about 20 to 55 or more years They may be obese

If these patients are ill, it is not from their hypertension However, the blood pressure is distinctly elevated, 160 to 185 or more systolic and 90 to 100 or more diastolic Some of the patients may have headaches. Nocturia is often present, particularly in the aging patients The heart may or may not be enlarged Obliteration of the radial pulse by pressure at the elbow reveals a definitely palpable thickened radial artery at the wrist Often flexion of the elbow will reveal that the arteries of the arm have lost a considerable part of their elasticity and do not contract with the flexed arm. They seem to be too long and are observed to be tortuous tubes pulsating in two planes

There is usually a response to rest by the blood pressure, perhaps a return to normal values will be revealed while the patient is asleep

Patients of this group have continuously a higher blood pressure than normal and more distinct changes in their retinal arterioles The arteriolar sclerosis is often graded 2 to 3 on a basis of 1 to 4 There is no, or at most minimal, angiospasm

Histologic studies of the muscle arterioles disclose a more uniform and more marked narrowing than is evident in the arterioles of group 1. In addition to narrowing of the lumen of the vessel, there may be thrombosis or occlusion of arterioles.

The urine usually contains albumin grade 1 to 2. The urinary sediment often contains hyaline and granular casts but rarely microscopic blood

As these patients pass into the aged groups of individuals, atherosclerosis is often superimposed, and any one of the cerebral, cardiac or renal accidents incident to this disease may occur The impression is gained that a person who has arteriosclerosis with hypertension is more susceptible to atherosclerosis than one who does not have arteriosclerosis

The clinical impression is gained that the patients of group 2 have a progressive disease. The hypertension of patients in group 2 more nearly corresponds to Volhard's designation of red hypertension

Diffuse Arteriolar Disease with Hypertension, Group 3. These patients are between 20 and 55 years of age, and men are more commonly affected than women

Generally there are headaches, feelings of fullness in the head, failures of vision, nosebleed, dizziness and unsteadiness of gait Often there is exertional dyspnea, cough, or other symptoms of left-sided heart failure. Nocturia and polyuria are common All of these symptoms may increase rapidly, then remain stationary for a time and then regress, but more often they tend to progress and increase in intensity

On examination these patients often have a general pallor, the so-called pale hypertensives of Volhard. There is often evidence of loss of weight. The blood pressure is high; 200 to 300 mm. of mercury systolic and 100 to 130 mm. or more diastolic are common. The radial arteries, however, may not reveal much arterio-

sclerosis. Often the sclerosis is not more than grade 2 on a basis of 1 to 4 The pulse rate is often increased. The heart is enlarged and the aortic second sound is accentuated Basal aortic systolic murmurs are common Edema of the ankles may be present after the patient has been on the feet for an hour or two The urine contains albumin, and often the presence of blood and a few casts may be revealed by microscopic examination. The concentration of urea nitrogen in the blood may be increased, depending on the degree of renal involvement More often there is present an inability of the kidneys to concentrate urine. The specific gravity of the urine has a limited range of variability (1 010 to 1,015).

An important criterion is the presence of angiospastic retinitis, together with definite sclerotic changes in the arterioles but no edema of the disks. In those who have had a remission from the progress of the disease there may be evidence in the retina of previously active retinitis, indicated by the obliteration of small arterioles. In such cases small arterioles of the retina undergo thrombosis, and a similar process may have occurred in the skeletal muscles.

On examination of the arterioles of the skeletal muscles, the lumina of the arterioles are decreased in size; definite cellular lesions and thrombosis are often present.

Diffuse Arteriolar Disease with Hypertension, Group 4 (Malignant Hypertension) This disease affects men more frequently than women The onset often occurs between the ages of 20 and 55 years Malignant hypertension has been reported, however, in older individuals and in children.

These patients are nervous, tense and weak and complain of visual disturbances or, more likely, faulty vision or definite failures of vision Headaches are often intense, and may approach in severity those caused from intracranial hypertension.

Dyspnea, palpitation, and some enlargement of the heart are often present The radial artery may be sclerosed, grade 2 or 3 on a basis of 1 to 4 Blood pressures range from 200 systolic upward measured in millimeters of mercury, and the diastolic may be 130 to 140

The urine contains albumin and often blood. In an occasional instance there may be profuse renal hemorrhages which are sufficient for blood clots to form in the ureters and cause acute colic. These clots are usually expelled spontaneously

The important retinal alterations are the marked spastic and organic narrowing of the arterioles with diffuse retinitis and edema of the disks The edema of the disks, if accompanied by the severe headaches, may require differentiation from increased intracranial hypertension

The arterioles of muscle obtained by biopsy reveal great narrowing of the lumina, cellular lesions and often thrombosis or occlusion

The prognosis is serious, only one of Wagener and Keith's patients lived as long as 40 months. Seventy-nine per cent were dead within a year However, one patient was alive 11 years after the first observation

Not in all cases of group 4 is the course so rapid Some patients even have periods with subsidence of the retinitis and with clinical symptoms which suggest remission Such cases belonging to group 3 were considered previously. Here again in group 4 spasm of the arterioles may determine whether the condition is progressive

Differentiation of Groups. The numbers 1 to 4 were employed by Wagener and Keith to avoid confusing terminologies The numbers 1 to 4 do not imply a progression from 1 to 4 in all instances of hypertension The number used designates or classifies the group of hypertension to which the patient belongs at the time of the first examination In reality, a patient belonging to group 1 may suddenly become a member of group 4, or a patient belonging to group 3 may become a member of group 1 and in very rare instances one who has hypertension group 4 may have a remission in the retinal findings and be classified as belonging to group 3.

Clinical differentiation of the four groups of essential hypertension, one group from another, may not be accomplished without difficulty. Patients of groups 1 and 2 have good retinal, cerebral, cardiac and renal function, whether the hypertension be labile, or high, with a tendency toward fixation In those belonging to group 3 there is evidence of dysfunction of one or several of the organs belonging to the arterial system, while in group 4 these functional disturbances become more effective and final failure may occur because of a simultaneous serious interference in the blood supply to the retina, brain, heart and kidneys. Difficulties of differentiation of one group from another arise when in a given case the disease progresses rapidly so that the patient passes from group 1 to group 4 in a short period

Examination of the ocular fundi is of considerable aid in determining the group in which an individual patient with hypertension belongs For practical clinical purposes those who have only purely organic changes in the arterioles of the retina belong to group 1 or group 2, while patients who show definite evidence of angiospasm belong in group 3 or group 4.

Thrombosis of the retinal veins is considered to arise either on the basis of organic changes alone or as the result of an infectious process (phlebitis) superimposed on a mild organic lesion Patients who have retinal venous thrombosis usually belong in group 2, although the other clinical and laboratory findings at times may justify their classification with hypertension of group 3 Cases of retinitis of arteriosclerosis usually can be placed in group 2 unless the retinitis can be shown definitely to be the residuum of a previously angiospastic type of retinitis.

Patients who have retinitis of angiospastic type, characterized by edema, cotton-wool-appearing exudates, and hemorrhages in the retina superimposed on a combination of sclerotic and spastic lesions in the arterioles, belong to hypertension group 3 or group 4. Patients who have cotton-wool-appearing exudates and hemorrhagic areas in the retina, but whose optic disks are not edematous, usually belong to group 3 The most characteristic feature of the disease in cases of hypertension of group 4 is measurable edema of the optic disks, which usually occurs, of course, in association with the other features of widespread angiospastic retinitis and in intracranial hypertension

Acute angiospastic retinitis is a part of vasospastic disease which is often present in the toxemias of pregnancy and active severe arteriolar sclerosis The ophthalmoscopic findings in these conditions vary from those of localized areas of edema of the retina, with cotton-wool-appearing exudates and hemorrhages, to that of retinitis, with diffuse edema of the retina In both acute angiospastic disease and toxemia of pregnancy, the retinitis may completely disappear under favorable circumstances, leaving as residuals varying grades of sclerosis of the retinal arterioles, depending on the severity and persistence of the underlying angiospasm. The features of an angiospastic disease which may clear up depend on the presence of angiospasm, generalized and localized irregular narrowing of the arterioles, and absence of organic changes in the vessel walls, such as visible thickening of the wall, exaggerated reflexes and arteriovenous compression. In an angiospastic disease when organic changes are developing in the walls of the arterioles, differentiation of group 3 or group 4 may be difficult or impossible without the presence of edema of the disks as regularly occurs in group 4

Wagener and Keith have expressed the belief that in the beginning of a toxemia of pregnancy the differentiation between retinitis of hypertension and "albuminuric retinitis" (nephritis) cannot be made except by the time element, since in most patients who show primarily a few cotton-wool patches and hemorrhages the characteristic appearance of albuminuric retinitis will later develop unless the pregnancy is terminated spontaneously or otherwise In the pregnant woman, as in the non-pregnant woman, the albuminuric type of retinitis is more often the result of diffuse arteriolar disease than it is of primary glomerulonephritis

organic changes in the vessel walls. However, they have observed that permanent organic changes at times may take place in the arteriolar walls after persistent spasm without the development of retinitis.

PROGNOSIS Many of those who belong to groups 1 and 2 live their normal life expectancy However, these patients often pass on to middle or old age, and then atherosclerosis develops, and thus heart failure, renal failure or strokes ensue

The prognosis for patients in group 3 and especially for patients in group 4 is grave. A death rate within one year of one third of those in group 3 and about two thirds of those in group 4 is in distinct contrast to that of 1 of every 10 in groups 1 and 2.

The prognosis in a group of patients who have hypertension from various causes has been forecast by Frant and Groen who reported a follow-up of 418 patients with hypertension (blood pressures above 155 systolic and 100 diastolic) who were re-examined after a period of 8 to 9 years. The death rate for men with essential hypertension exceeded the normally expected death rate in the same age groups by 102 per cent, for the women this figure was 91 per cent Chronic nephritis increased the death rate in men by 587 per cent and in women by 150 per cent. Hypertension related to toxemia of pregnancy carried a mortality of 155 per cent in excess of the normal The total excess mortality for patients with hypertension of all types was 233 per cent for the men and 201 per cent for the women The mortality increased with increase of both systolic and diastolic blood pressure.

The condition of the fundus of the eye is a better guide for the prognosis of hypertension than the increase in blood pressure. In the cases studied by Frant and Groen heart disease, albuminuria and diabetes appeared to reduce the expectation of life even more for women than for men Hypertension accompanied with obesity appeared to be prognostically more favorable than the same hypertension in patients whose weight was normal or low Hypertension in young subjects carries a relatively shorter life expectancy than high blood pressure in old age Heart disease is first among the causes of death of patients with hypertension, it accounts for 40.9 per cent, next comes carcinoma (16.4 per cent), followed by uremia (14 9 per cent) and apoplexy (8.6 per cent) Apoplexy as cause of death was almost five times as common among women (14.2 per cent) as among men (3 1 per cent). The cause of death could not be ascertained for 9 4 per cent

The prognosis seems to be better since the advent of new drugs.

Arteriosclerosis and Atherosclerosis With and Without Hypertension. Hypertension with an increase in diastolic pressure is probably not present without disease of the smaller arteries or arterioles Indeed on general examination there may be evidence present of disease of the larger and smaller arteries without an accompanying hypertension Determination of the basal blood pressure reveals a pressure within the limits of normal for the age group to which the patient belongs However, these observations, if made in the presence of manifest cardiac or renal disease, may be diagnostically misleading, for such patients may have had a very low normal basal pressure prior to the development of manifestations of cardiac or renal disease Such observations require definitions of arteriosclerosis, arteriolar sclerosis and atherosclerosis

Definitions of arteriosclerosis, arteriolar sclerosis and atherosclerosis are difficult, for these terms have been variously employed to mean different forms and degrees of vascular disease as well as the same vascular disease

The term arteriosclerosis (hardening of the arteries) in its broad use refers to degenerative vascular changes which are not due to syphilis, rheumatic fever or specific infectious diseases, and the term does not include the conditions known as thromboangii-

tis obliterans, periarteritis nodosa and lupus erythematosus. Arteriosclerosis designates a condition marked by loss of elasticity, thickening and hardening of the arteries. Appropriate adjectives designate the region of the body most profoundly affected, for instance, cerebral, coronary, or in the case of widespread disease, general arteriosclerosis. A special form in medium-sized and smaller-sized arteries characterized by a primary necrosis and calcification of the medial coat is termed Monckeberg's sclerosis.

As the term arteriolar sclerosis commonly is used, it designates changes in the *smaller arteries* and *arterioles* which are characterized by endothelial hyperplasia, thickening and hyalinization of the intima and hypertrophy of the media of the arterioles of the kidneys and other viscera, and which are more uniformly distributed in the arterioles than is either arteriosclerosis or atherosclerosis in the larger arteries. Arteriolar sclerosis is always associated with hypertension. These arteriolar changes are of the type of vascular disease responsible for essential hypertension (groups 1 to 4) of Wagener and Keith.

Atherosclerosis affects the *large* and *medium-sized arteries,* such as the aorta and the coronary and cerebral vessels, the arteries to the arms and legs, and the larger peripheral arteries. The condition is characterized by intimal thickening due to lipoid atheroma, fibrosis, calcification, necrosis and hemorrhage. This is the type of arteriosclerosis which involves the coronary and cerebral arteries and is often responsible for arteriosclerotic heart disease and cerebral apoplexy in those who do not have hypertension.

Atherosclerosis is common after the age of 40 years. There is an increasing frequency with subsequent decades.

Heart disease, renal disease and cerebral disease due to arteriosclerosis and atherosclerosis are much more frequent among men than among women.

Hypertension is present in about one half of all the men and in about three fourths of all the women who have these degenerative forms of heart disease. Arteriosclerotic heart disease in the absence of hypertension suggests that hypertension is an aggravating factor and not the cause.

Arteriosclerotic heart disease develops with unusually high frequency among diabetic patients and those who have familial xanthomatosis with hypercholesterolemia, myxedema, or chronic glomerulonephritis and obesity.

The theories of the etiology of arteriosclerosis and atherosclerosis are concerned primarily with whether or not the disease is a process of aging or with conditions incident thereto such as metabolic disorders, inherited or acquired.

The life span of man no doubt does change according to various and unknown conditions arising within his own body or as the result of environmental conditions. It would be well to wait, before conclusions are drawn concerning the increasing span of human life as well as the purported increase in the incidence of arteriosclerosis and hypertension, to see whether these might not be just passing phases in the evolution of the species. To gloat over any particular achievements of this generation over the immediately former generations might prove to be premature.

In a similar vein the tempo of modern industrialized civilization is indicted as the cause of hypertension and hardening of the arteries. A comparison of the tempo and the emotional tensions of men who lived 25,000 or more years ago is not available. If such were available, might it not be just possible that these men and women had many tensions unknown to us now? Did they not have arteriosclerosis and hypertension often resulting in sudden death? One can be sure that if they did have angina pectoris or strokes, they were not accorded protection in bed for prolonged periods of time. The prolongation of such a life by bed rest alone is hardly worthy of praise as a medical accomplishment.

Transient, and occasionally permanent, hypertension may follow repeated, powerful emotional experiences involving fear, anxiety and hostility. A characteristic hypertensive personality and a distinctive psychiatric pattern have been described.

Hypertension is slightly commoner in women than in men. Hypertensive (and arteriosclerotic) heart disease is much more frequent in men.

GENETICS AND ATHEROSCLEROSIS Adlersberg, Parets and Boas have recorded 35 families with xanthoma and the relationship of this condition to hypercholesterolemia, coronary artery disease and related stigmas It appeared to these authors that a common factor for some patients with coronary atherosclerosis may be a hereditary disturbance of cholesterol metabolism manifested by elevated serum cholesterol. Familial xanthomatosis is the severest form of the inherited disturbance. Xanthomatous lesions develop only in patients who carry two abnormal genes for cholesterol, that is, they are homozygotes. Atherosclerosis is frequent in such persons. These authors believe as others do that some patients with uncomplicated coronary artery disease are probably affected with a mild form of disturbed lipid metabolism. They carry one abnormal gene for cholesterol; that is, they are heterozygotes Derangement of cholesterol metabolism helps explain the familial incidence of coronary artery disease and also accounts in part for its development in many persons less than 50 years of age.

METABOLISM The only constant factor in all the metabolic theories of arteriosclerosis is that cholesterol and other lipids play a common role in the production of the disease It is thought that the initial disturbance in atherosclerosis is one of solution or dispersion of cholesterol in the blood, due either to hypercholesterolemia or to alteration in other substances in the blood which diminish the solubility of cholesterol.

There are large amounts of cholesterol esters and free cholesterol in atheromatous lesions. The quantity present exceeds that which could be formed by local degeneration The concentrations of lipids in these lesions correspond to their concentration in the plasma.

Gofman and associates have pointed out that it is not the total plasma cholesterol which correlates with vascular sclerosis, but rather the presence and quantity of an abnormal cholesterol-containing lipoprotein

Since dietary cholesterol occurs in foods of animal origin with particularly desirable nutritional value (for example, meat, eggs and milk), it seems unwise on the bases of the present evidence to condemn use of these foods if there is risk of sacrificing the foundations of sound nutrition This is particularly significant and in accord with the observations of Keys and associates who observed that the serum cholesterol level of "normal" men is not significantly related to differences in the habitual cholesterol intake over a range of something like 250 to 800 mg per day.

Premature atherosclerosis occurs in diabetes However, the specific metabolic or endocrine factor in diabetes which predisposes to atherosclerosis is uncertain

OBESITY AND ATHEROSCLEROSIS Faber and Lund studied 408 aortas from necropsy material in hospitals and the medicolegal institute of Copenhagen. Two hundred and ninety-five of the 408 patients, 240 men and 168 women, from whom the aortas were obtained had been of normal weight and 113 had been obese Two hundred and eighteen of normal weight and 41 obese persons had had normal blood pressure, 77 of normal weight and 72 obese persons had had hypertension The great increase in the degree of sclerosis with rising age makes it necessary to eliminate the age factor from the evaluation of the sclerosis. The logarithm of the cholesterol and calcium content of the vessel wall and the dry weight of the tissue rises rectilinearly with age To eliminate the factor of age the formula for this line had been calculated for these three factors. Distribution curves for the dry weight, the total cholesterol content and the calcium content of the intima and media of the aorta around the calculated normal line for the four groups of persons studied [illegible] Comparison of these [illegible] bove what should be [illegible] of the factors studied when the presence of hypertension is taken into account

MANIFESTATIONS The manifestations of arteriosclerosis or atherosclerosis de-

pend on the individual arteries affected and their distribution to various members, organs or systems of the body. These symptoms are discussed in association with the organs or systems affected.

Symptoms arise when there is interference with the blood supply to the part caused by occlusion, partial or complete, or rupture of the artery Associated or unassociated with partial or complete occlusion or rupture of an artery, may be disturbances in conduction and rhythm of the heart, in cerebral functions, in digestive functions, and in locomotion attributable to atherosclerosis.

On examination either arteriosclerosis or atherosclerosis may be found without the demonstrable presence of the other. Arteriosclerosis often will be accompanied by hypertension Arteriolar sclerosis will always be accompanied by hypertension These conditions are diagnosed by ophthalmoscopic examination.

Examination when the arm is flexed at the elbow reveals a visible tortuous brachial artery which pulsates in two planes, for the artery has lost its elasticity. Often palpation of such an artery reveals small, hard, irregular plaques. The pulsations in such arteries, especially when those of the legs are involved, may reveal decreased or absent pulses

The roentgenograms often reveal the presence of radiopaque material along the course of the larger arteries in all parts of the body, especially the aorta, and the *pelvic vessels.*

The diagnosis of arteriosclerosis and atherosclerosis depends on the symptoms and physical signs resulting from the diminishing or the discontinuing of blood flow to the affected part

The peripheral arteries can be palpated, and often calcification in their walls can be demonstrated by roentgenologic examination

The presence of arteriosclerosis in a youth suggests the possibility that diabetes mellitus is present

Angina Pectoris. The immediate cause of angina pectoris is insufficiency of the coronary circulation

The causes of insufficiency of the coronary circulation, as enumerated by White, are (1) diseases of the coronary arteries due to atherosclerosis, infection, thrombosis or embolism, (2) the coronary arteries may be blocked at their mouths, partially or completely, by swelling and inflammatory reaction of the aortic wall in syphilitic aortitis, or by vegetations on the aortic intima or extending up from the aortic valve cusps in bacterial endocarditis There may be (3) marked aortic regurgitation with very low diastolic blood pressure, it is an ample diastolic blood pressure that normally maintains an efficient coronary circulation, for during systole the coronary arteries are compressed. There may be (4) marked aortic stenosis with low pulse pressure and limited output per beat which, doubtless with the added effect of suction by the forceful narrow jet of blood directed up the aorta with each heart beat, cuts down the coronary circulation There may be (5) severe anemia, pernicious or secondary, with insufficient oxygen in the blood carried to an active myocardium, even though the coronary arteries themselves are fairly normal There may be (6) too great a demand on the heart muscle, as in excessive exertion or thyrotoxicosis, so that the coronary circulation, though adequate at rest, is unable to maintain a sufficient blood flow to the myocardium under these circumstances There may be (7) spasm of the coronary arteries lasting a few minutes at a time in patients who have relatively normal vessels

Hypotheses of Pain in the Heart. There are two often quoted hypotheses of the origin of cardiac pain ischemia of heart muscles, and tension on the coronary arteries The following paragraphs summarize the observations of Blumgart on the origin of cardiac pain due to ischemia.

Ischemia. In the syndromes of angina pectoris, coronary failure and acute myocardial infarction, cardiac pain is an expression of a relative disproportion between the demands of the myocardium for blood and the decreased supply it receives through the coronary arteries The changes in the myocardium resulting from this disproportion depend on the duration of the ischemia If the ischemia is brief, the pain is brief, as in

angina pectoris, and no permanent myocardial damage may occur. If the ischemia is more prolonged, the pain is more severe and prolonged. If the duration of complete obstruction is longer than 15 minutes, irreversible changes, that is, myocardial necrosis, are produced, notwithstanding re-establishment of normal blood supply. When the blood supply has been interrupted for 40 to 45 minutes, widespread myocardial infarction is witnessed during the succeeding days, even though blood flow through the coronary arteries is not obstructed.

Cardiac pain is precipitated by effort, emotion and other states which increase the work of the heart, and is relieved by rest and other measures which lessen the work of the heart. Cardiac pain may be induced by breathing low concentrations of oxygen. All of these facts support the concept that cardiac pain is due to ischemia. The structural changes in the coronary arteries and in the myocardium must not be considered the exclusive cause of cardiac pain, but rather as constituting the stage on which various factors may operate. Thus vasoconstriction or absence of vasodilatation, effort, anemia, tachycardia or shock with its lowered blood pressure may act as precipitating agents in the production of pain in a heart whose circulation is already compromised by arterial obstruction.

Tension. According to Gorham the arguments for the tension hypothesis of cardiac pain have been advanced and supported by such evidence as the occurrence of coronary occlusion without pain. Pain is more frequent in the presence of acute fresh thrombosis and infarction and is less frequently encountered in old fibrous infarcts without actual thrombosis.

Pain is known to arise from blood vessels, owing to tension on the walls of arteries in instances of embolism of the peripheral arteries, in dissecting aneurysm and in migraine.

Tension is the commonest cause of pain, as noted in inflammatory lesions and in the colics produced by smooth muscle contraction in hollow organs.

Pain may be produced in the human heart affected with coronary sclerosis and the anginal syndrome by the injection of epinephrine.

Angina pectoris occurs predominantly in men. The disease occurs in women usually in association with diabetes or hypertension. The average age of onset is 56 years for men and 58 years for women.

There are no convincing data to prove that angina pectoris affects particularly those whose work subjects them to continuous mental tension. Angina pectoris occurs in individuals of all races and all social and economic strata.

The genealogic history often discloses that the patient's progenitors, in one or more lines of the family, suffered from angina pectoris. Of the affected line or lines of the family, the members who have angina pectoris are usually short and stocky, overweight, short-necked with barrel-shaped thorax.

These patients are aggressive, ambitious, serious-minded persons who possess deep emotional reactions.

PATHOLOGY. The pathologic changes are varied. They are those of any disease or condition which causes a narrowing and occlusion of the lumina of the coronary arteries. Diseases and states causing coronary narrowing are atherosclerosis, syphilitic aortitis, aortic valvular disease, reduction in aortic blood pressure, pulmonary embolism, shock states, reduction in oxygen content of the blood as in anemia, and arterial anoxemia, as caused by pulmonary or congenital heart disease, low atmospheric oxygen tension, and drugs.

SYMPTOMS. Angina pectoris is characterized by paroxysmal attacks of pain or oppression, situated retrosternally, and extending commonly to the precordium and left pectoral girdle, usually to the arm.

The pain in angina pectoris is as a rule dull and throbbing, is produced by effort, and is relieved immediately by rest or nitrites. The pain of acute myocardial [illegible]

[illegible] nged

[illegible] the

syndrome. The pain of angina pectoris rarely occurs while the patient is at rest

In such a patient, if the pain or oppression cannot be reproduced by exertion or sexual intercourse, the diagnosis of angina pectoris is dubious

The pain during a paroxysm of angina pectoris is usually situated at or behind the middle or upper third of the sternum, centered at the level of the third or fourth rib. Occasionally the pain is more extensive and covers most of the precordium A pain that is situated at or near the cardiac apex or to the left of the cardiac region is not due to angina pectoris

The pain of angina pectoris, when it is severe, tends to extend to the arm, neck, and occasionally to the jaw. In its most precise form the pain extends across the precordium to the left shoulder and upper medial side of the arm and may extend as far as the elbow, the wrist or the fingers It may affect the wrist and fingers without involving any other portion of the extremity Sometimes the pain starts in the left wrist, arm or shoulder and travels toward the sternum It may commence in the sternal region and pass directly toward the left scapular region.

The more severe pain of angina pectoris may be described as constrictive, pressing, choking or expanding. There may be a sense of a vise around the thorax Often the pain resembles that of gaseous distention and the patient tries to belch *and takes baking soda in attempts to obtain relief The pain may or may not* compel the patient to stop activity and to rest

A common characteristic reaction of the patient to the pain is the fear of immediate impending disaster, termed angor animi

Duration of the attack of angina pectoris which occurs during physical activity is less than 5 minutes. The attacks which occur while the patient is at rest last longer, often from 5 to 15 minutes or up to a half hour. When severe pain lasts for more than a half hour, an acute coronary occlusion is usually present

The frequency of the attacks of angina pectoris varies, the intervals depending to some extent on avoidance of the factors which excite the attacks Attacks may come each day, without apparent cause, or after performance of the essential physiologic functions

Walking, especially against cold wind, or walking rapidly is the commonest form *of bodily exertion producing the pain of angina pectoris* Under favorable walking conditions on level ground, one of these patients may walk a mile or more without discomfort Some patients have pain when they walk for only a short way during the early morning hours, and then are able to perform rather heavy manual work the rest of the day

After a meal less effort is required to provoke an attack than when the stomach is empty Straining at stool is sometimes responsible for an attack. Any or all emotional upsets, such as heated arguments, the excitement of card playing, grief and anger, and a variety of petty annoyances may induce an attack Not infrequently cardiac pain occurs during sexual intercourse

Excessive insulin dosage may induce attacks of angina pectoris

EXAMINATION There are no abnormal physical signs in patients who have uncomplicated angina pectoris

The blood pressure in about half of those who have angina pectoris is within the normal range The rest have hypertension

Ordinarily electrocardiographic studies are made while the patient is free from pain; then the tracings are often entirely normal. There may be abnormalities, however, of the T and Q waves or of the QRS complexes

Tests of Coronary Reserve and Coronary Insufficiency. There is a range in which increases and decreases of the amount of the coronary blood flow to the myocardium occur without the production of pain This range represents the coronary reserve. In those who have an impaired range of adjustment of the coronary *circulation*, the coronary reserve is diminished. Attempts have been made to establish for diagnostic purposes tests or methods which measure the degree of

insufficiency of the coronary circulation These tests are (1) exercise in graduated amounts and (2) the anoxemia test. Usually these tests are not required, and in a patient who has definite coronary disease, performance of any test is undesirable (see Tests of Cardiac Function, page 704).

The patient who has angina pectoris may scarcely be inconvenienced, or his activity may be involuntarily so restricted that he is a chronic cardiac invalid. Most patients, for at least a few years after the initial episode, remain capable of earning their livelihood at their usual occupation as they become accustomed to the range of bodily activities which can be performed without having pain

DIAGNOSIS The essential diagnostic features of angina pectoris are (1) the paroxysmal occurrence of the pain, (2) its brief duration, (3) its characteristic location, radiation and quality and (4) its precipitation by effort and relief by rest or nitrites

The diagnosis of angina pectoris should be made with reservation in a woman unless there is evidence of an underlying disease capable of producing coronary insufficiency

In a series of cases Parker, Dry, Willius and Gage observed that the average age at onset of the anginal syndrome was slightly earlier for men than for women. While there was wide variation in age of the patients at the onset of symptoms, 88 per cent of the patients were from 40 to 69 years of age. The ratio of men to women was 4 3 1

The highest mortality rate occurs in the first year following the establishment of the diagnosis of coronary arterial disease with angina pectoris Thereafter the yearly mortality rate is less than it was in the preceding year. The survival rates of women having the anginal syndrome are greater than those of men

When corrected for deaths not due to angina pectoris, the five-year survival rate of patients 30 to 39 years of age with the anginal syndrome is definitely shorter than when the disease manifests itself later in life

Such associated conditions as cardiac hypertrophy, well-defined hypertension, previous cardiac infarction, congestive heart failure and significant electrocardiographic abnormalities are clearly related to a higher mortality rate and lower survival rates

Acute Coronary Occlusion and Myocardial Infarction. An acute thrombotic occlusion of a major coronary artery by the development of a thrombus or by an intimal hemorrhage with swelling of the arterial wall, or by an embolus, is termed coronary thrombosis

The injury or necrosis of a portion of heart muscle because of an interruption or curtailment of its blood supply is infarction of the myocardium or cardiac infarction.

Acute coronary occlusion and myocardial infarction are not always associated Coronary occlusion may occur without an ensuing infarction, and myocardial infarction may develop in the absence of an acute coronary occlusion The same symptoms are associated with myocardial infarction whether or not it is due to an acute coronary occlusion

There has been a progressive increase in the reported incidence of coronary occlusion This rising curve of reported mortality has not yet leveled off and it will not level off until clinical judgment in diagnosis supersedes diagnosis made by the electrocardiographic machine A person can die from some other cause despite the fact that he has a bad heart.

There is great uncertainty, however, as to whether this reported increase is real or is due to a statistical mirage produced by increased knowledge and more accurate diagnosis of coronary thrombosis The increase in the span of life due to the reduction in diseases of childhood and other infections and to other advances in medical knowledge has brought a larger proportion of the population to the age

groups in which death from arteriosclerotic coronary thrombosis occurs There h[illegible] always been a large number of individuals in the age group in which death fro[illegible] arteriosclerosis and coronary thrombosis is frequent, and probably there has bee[illegible] but little change in the mortality rates from arteriosclerosis or its complications [illegible] the total numbers in this age group.

Arteriosclerosis of the coronary arteries is usually responsible for acute coronar[illegible] occlusion The occlusion is caused by intimal hemorrhage and subsequent forma[illegible] tion of thrombus originating secondarily in an atherosclerotic plaque or in ruptur[illegible] of an arteriosclerotic abscess.

There is a basic relationship of hypertension and arteriosclerosis to acute coronary occlusion This relationship seems to be founded on observation that hypertension intensifies or accelerates arteriosclerosis. In some instances it seems that hypertension predisposes to the arteriosclerosis, and as a result of arteriosclerosis there are an intimal hemorrhage in arteriosclerotic plaques, formation of thrombus, and coronary occlusion There are other conditions which seem to predispose to arteriosclerosis, such as diabetes, familial hypercholesterolemia with xanthomatosis, myxedema, and polycythemia to mention but a few. Then there are those conditions which may seem to be important in the production of coronary occlusion and these may be separated into remote and immediate causes The *remote causes* may be enumerated (1) At least 9 of every 10 who have acute coronary thrombosis and myocardial infarction are between the ages of 40 years and 70 years When younger persons have acute coronary thrombosis, death often occurs suddenly (2) Most of those who have coronary thrombosis are men (3) Occupation is secondarily an important predisposing factor, for the reason that those who are temperamentally fitted for occupations requiring nervous tension are those who would have coronary thrombosis anyway (4) As statistical data accumulate, racial predilections become less obvious (5) Morbid heredity appears to be a remote etiologic factor predisposing to the occurrence of general arteriosclerosis, and therefore of coronary sclerosis and occlusion. (6) Patients who have acute coronary thrombosis often are of short, stocky stature, have some obesity, a thick short neck and a barrel-shaped thorax These somatic attributes are inherited The disease occurs, however, in all the somatic types.

Like the remote causes for coronary occlusion which have been enumerated some of the so-called immediate causes have only slight demonstrable relationship to coronary occlusion The actual occlusion of a coronary artery precedes the symptoms of the attack often by days Efforts by the physician to discover the immediate causes by recording the events or activities immediately preceding an acute coronary occlusion are futile The history will reveal (1) Physical exertion may be indirectly related to the development of a myocardial infarct after an acute coronary occlusion has already occurred (2) Emotional strains must be interpreted in terms of their effect on the individual and his reaction to them Like physical exertion, emotional stress cannot have a definite value assigned to it (3) Surgical operation may be followed by an acute myocardial infarction. Those affected usually are more than 50 years old and often past 60 years Almost always there is evidence in these hearts that there was pre-existing severe coronary arteriosclerosis, and often a previous coronary occlusion. (4) A patient who has had a certain attack of coronary occlusion confronts increased risk on subjection to surgical operation (5) There is no good evidence that the use, even the excessive use, of tobacco or overindulgence in alcoholic beverages contributes, either remotely or immediately, to the development of coronary artery diseases or acute coronary occlusion

PATHOLOGY A common cause of coronary thrombosis is the formation of a thrombus on an arteriosclerotic intimal plaque

Coronary occlusion occurs with equal frequency in the left anterior descending artery and the right circumflex artery. Occlusion of the left circumflex coronary artery

occurs less frequently Cardiac enlargement or hypertrophy occurs in at least two thirds of those who have had cardiac infarction However, the heart often remains of normal size after acute coronary occlusion. Cardiac hypertrophy is seen pathologically and cardiac enlargement is observed clinically in many cases of coronary occlusion

SYMPTOMS In most of those who have not had angina pectoris, premonitory thoracic pain precedes coronary occlusion by one to several days or weeks. Those who have had angina pectoris realize from the beginning that the pain of coronary occlusion is different from the pain of angina pectoris. It is distinctive because for

only to recur for hours or days at irregular intervals thereafter.

In some patients there is intense pain for one or two hours, after which the patient may feel and appear perfectly well Only electrocardiographic studies disclose that the pain was due to an acute myocardial infarction The pain of acute myocardial infarction, like that of angina pectoris, may extend to the shoulders and both upper extremities, to the neck and jaw, and to the interscapular region.

After myocardial infarction the patient who has not previously had pain may become subject to paroxysms of angina pectoris. These may occur as a result of *slight activity, meals or emotional states. Other patients previously affected by* attacks of angina pectoris may be completely relieved of their pain after they recover from the acute myocardial infarction

When myocardial infarction occurs without pain, it is often characterized by a sudden development of weakness, shock, pulmonary edema or congestive heart failure However, milder manifestation of myocardial infarction occurs during which the patient complains of transient cold sweats and weakness, and of feeling sick, dizzy, faint or nauseated Vomiting and thirst are common

When shock occurs, it comes soon after the onset of the pain and lasts from a few hours to one or two days or until death. If the patient recovers from the shock state, there is an awareness of pressure pain over the sternum or precordium, pain or weakness in the arms or forearms, or numbness in the wrist or fingers The persistence of shock is followed by congestive heart failure.

In some patients who have myocardial infarction the first manifestation is an abrupt attack of pulmonary edema which appears suddenly and without warning Sometimes, however, it follows hours or days after premonitory substernal pain or recovery from the earlier stage of shock

A myocardial infarction which commences with massive pulmonary edema may terminate rapidly or, if improvement supervenes, there may remain left ventricular failure characterized by recurrent cardiac asthma, orthopnea or dyspnea on slight exertion As time passes and subsequent infarctions occur, evidences of right-sided congestive heart failure ensue

EXAMINATION On examination there may not be present any abnormalities in appearance or behavior except that the patient complains of persistent thoracic pain Often there are evident weakness, perspiration, nausea, or abdominal distention and breathlessness

In other patients who have myocardial infarction the physician may witness all the known emotional and physical acrobatics which have been and are practiced by mankind when recipients of torture and pain The emotional response of terror dominates Generally, however, the patient is listless or prostrated. The responses to questions are brief. There is evident desire on the part of the patient to be left alone and not be burdened with answers to questions or examinations. The skin of the face is of ashen pallor and the lips and finger tips are faintly cyanotic. A bluish red mottling of the skin (cutis marmorata) is common. The hands and feet and the tip of the nose are cold and moist

In acute pulmonary edema the patient is propped up in bed, gasping for breath, and neck veins are engorged, the lips and skin distinctly cyanotic There is a cough and the sputum is frothy and pink with blood If death is impending, there is a copious foamy pink-stained fluid bubbling from the mouth and sometimes from the nose Pulmonary edema often clears rapidly after an opiate or bloodletting (500 ml) It may persist intermittently for several days despite any known therapeutic measures

On percussion of the cardiac borders and palpation of the apical impulse in cardiac infarction there may be no evidence of cardiac enlargement In the presence of congestive heart failure the heart may be so enlarged that this is readily determined by percussion and palpation.

Auscultation may reveal enfeebled heart sounds The first sound is usually faint and low pitched A soft blowing murmur at the apex is heard in instances of second or multiple infarction in which there is some degree of left ventricular dilatation and subsequent mitral insufficiency An aortic systolic murmur may be heard which is attributed to arteriosclerotic changes in the ascending aorta When hypertension persists despite the myocardial infarction, the second aortic sound is accentuated or reduplicated In left ventricular failure accompanied by pulmonary hypertension the second pulmonic sound is accentuated and may be louder than the second aortic sound

Gallop rhythm and pericardial rub if present are best heard at or slightly medial to the apex or in the fourth interspace near the left sternal border. The gallop rhythm is usually present when there is heart failure It most frequently appears in the first day or two after the infarction and disappears as cardiac function is improved and the pulse decreases

An intermittent pericardial rub is present in about one fifth of those who have cardiac infarction It may first be audible a few hours after the attack, but most commonly on the second or third day In large infarcts or progessive myocardial infarction a pericardial rub persists continuously for many days *It is usually heard* along the left border of the sternum, but it may be audible over a large part of the precordium The rub indicates an acute fibrinous pericarditis and not necessarily anterior infarction

The pulse rate often is between 100 and 110 per minute A sinus bradycardia with a pulse rate of 60 per minute may be present

In cardiac infarction there is first a rise in blood pressure. This is followed by a fall in blood pressure which occurs sometimes after several hours, but more often on the second day after the attack. The decrease in blood pressure is by progressive decline, and rarely it is delayed for a week. In those in whom it results early the blood pressures may be less than 90 or 80 mm of mercury In about one third of the patients who have had hypertension before myocardial infarction, the blood pressure remains within a normal range for at least many months thereafter In these there is no evidence of a diminished cardiac output. Some never regain their hypertension.

Acute cardiac infarction is accompanied by fever which begins within a few hours up to two days The temperature ranges from 100 to 102 F (37 7 to 38 8 C) or higher It usually reaches its peak on the third or fourth day and continues so for seven or eight days.

An increase in the *leukocyte count* occurs on the second or third day, only occasionally within hours after the infarction. The count varies from 12,000 to 15,000 or 20,000 per cubic *millimeter of blood. The leukocytosis disappears* by the end of a week. There is an associated polynucleosis with a slight shift to the left. A persistence of a high leukocyte count suggests the development of a complication such as pulmonary or other embolism, bronchial pneumonia, or progressive myocardial *infarction.*

The rate of sedimentation of the erythrocytes is almost always increased after an acute myocardial infarction This test is of questionable diagnostic value since the sedimentation rate may be increased in almost every illness which affects the human race and at times when no illness can be assigned.

Chemical examination of the blood may reveal hyperglycemia and azotemia which may prove to be transient unless present prior to the attack.

The examination of the urine usually reveals no significant abnormality indicative of cardiac infarction Hematuria may appear as a consequence of renal infarction, secondary to emboli arising from left ventricular mural thrombi

Electrocardiographic Changes in Acute Cardiac Infarction. The electrocardiographic changes following cardiac infarction, when studied early and by serial examination at brief intervals, may be specifically diagnostic of the disease. When coronary occlusion occurs without infarction, there may be no significant electrocardiographic abnormality despite the occlusion

Electrocardiograms are often normal with slight coronary heart disease, but in advanced disease they usually show changes in the Q and T waves and often in the S-T segments They may show the presence of intraventricular block and low voltage, uncommonly there is auriculoventricular block Abnormal left axis deviation is not common unless there is an associated hypertension

In the presence of coronary artery occlusion Q waves tend to appear or are exaggerated and the T waves may be deformed, becoming low, inverted, or of unusual shape A few hours after onset a high origin of the S-T segment from the descending limb of the R wave in lead I or lead III with a corresponding depression of this S-T segment in the opposite lead, that is, lead III or lead I appears With this change in the S-T segments and T waves there appears a distinct Q wave in the QRS complex, or an exaggeration of it if already present, in lead I when the S-T segment is elevated in lead I and in lead III when the S-T segment is elevated in that lead In the apex lead (lead IV) the R wave tends to disappear, the S-T segment is much elevated in the early stages and the T wave becomes inverted in the Q_1T_1 type of electrocardiogram, while the QRS and T waves remain unchanged or are exaggerated and the S-T segment occasionally is definitely depressed at first in the Q_3T_3 type After a few days the S-T segment begins to flatten out but there remains either in lead I or in lead III an inverted T wave The flattening or inversion of the T wave may persist, or the deflection may gradually become normal again after weeks or months, associated with recovery and repair of the infarct The abnormality of the Q waves often is permanent and remains as mute evidence of an old infarction

Infarction of the anterior wall of the left ventricle is generally attended by high origin and later inversion of T_1, development of Q_1, absence of R_4, and inverted T_4, while infarction of the posterior wall of the left ventricle is likely to be followed by high origin and later inversion of T_3 with development of a prominent Q_3 and a relatively normal lead IV The QRS and T waves in lead II may not be found altered, but it is common for T_2 to be flat or inverted during the course of the acute myocardial infarction and sometimes for months or years thereafter in either the anterior wall type of infarction of the posterior wall type, more commonly in the anterior wall type, the more marked and persistent the changes in lead I or lead III, the more abnormal is T_2

Electrocardiography of a suspected coronary heart disease is not complete without at least one chest lead and several authorities believe that it is essential to take even as many as 6 and more recently 12 chest lead records, especially in doubtful instances where there is need to explore to establish the lead point nearest to the area of damaged muscle Thus the routine cardiac apex lead (lead IV) may demonstrate or confirm by absence of the R waves or by elevation of the S-T segments or by inversion of the T waves the presence of an infarct of the anterior wall of the left ventricle without bothering with any other precordial lead, but a lateral wall or septal infarct may require leads further to the left or to the right, and a posterior wall infarct may be shown only, so it is said, by an esophageal lead

In some instances the electrocardiographic changes may not be significant of acute myocardial infarction and thus do not disclose its situation This is particularly

true when there have been multiple infarcts. Also the presence of a bundle-branch block, extensive pericarditis, the administration of digitalis, or a decidedly transverse or vertical heart, each or in combination, will obscure the electrocardiogram so that localization of the infarct is impossible.

DIAGNOSIS OF ACUTE CORONARY OCCLUSION AND MYOCARDIAL INFARCTION In a middle-aged or older man severe, oppressive pain over the precordium or over the lower part of the sternum or more extensively over the anterior part of the thorax, lasting at least a half hour, and not relieved by the administration of nitrites, indicates in most instances acute myocardial infarction.

Myocardial infarction is suspected in a middle-aged person when unexpectedly and without apparent cause there are severe prostration and collapse

When an aging person begins to experience attacks of nocturnal dyspnea or dyspnea on mild exertion, and when these symptoms suddenly become more severe, and there is perhaps enlargement of the liver, engorgement of the peripheral veins or peripheral edema, the possibility of a recent cardiac infarction is likely.

In many instances of acute cardiac infarction the thoracic pain may have been mild and transient and will have been forgotten But if there should be the history of a sudden and unexplained extreme fatigability, weakness, attacks of dizziness or syncope, indigestion, short episodes of dyspnea and pallor or cyanosis, palpitation and a cardiac arrhythmia, myocardial infarction is a likely diagnostic consideration.

There may be, however, certain electrocardiographic findings which in themselves justify the diagnosis. The electrocardiographic studies are invaluable in the diagnosis of cardiac infarctions without pain.

PROGNOSIS IN ACUTE CORONARY OCCLUSION AND MYOCARDIAL INFARCTION The duration of life when acute cardiac infarction occurs is unpredictable because from the instant the infarction occurs there is the constant threat of sudden unexpected death, then and during convalescence and even thereafter during the lifetime of those who survive for years The mortality rate is 40 to 50 per cent within 4 to 6 weeks after onset

It is probable that if the milder instances of the disease were identified, the mortality rate from first attacks of acute myocardial infarction would not exceed 1 in every 10 It seems that survival is the rule after the first occlusion or even after successive occlusions which have given no symptoms.

Myocardial Infarction and Sudden Death. Visceral embolism and peripheral embolism associated with myocardial infarctions are common complications and often the immediate cause of death These emboli, in the following order of frequency, affect the lungs, the brain, the kidneys, the spleen, the intestinal tract and the arteries The embolus often lodges at the bifurcation of a peripheral artery. The commonest site is the femoral artery at the origin of the profunda femoris, and the next commonest sites are the common iliac, axillary and brachial, and popliteal arteries and the aorta Peripheral embolism which does not cause immediate death is often characterized by acute and excruciating pain, blanching of the affected area of skin, loss of sensation, coldness of the extremity, loss of arterial pulsation and later loss of motion of the affected muscles. However, it is important to know that peripheral embolism may not be accompanied by pain. In the course of serious or critical illnesses and particularly when the patient has severe pain, embolism may occur without complaint and the patient be found dead by a member of the family or an attendant of the sick Among the causes of sudden death are massive pulmonary and cerebral embolisms

The weakened ventricular wall, the result of infarction, may permit the formation of ventricular aneurysm

Sudden death may be caused by the rupture of a cardiac aneurysm Sudden death from rupture of the heart in the absence of cardiac aneurysm is of relatively common occurrence in the first few weeks after acute myocardial infarction

Ventricular fibrillation is a common cause of death after infarction.

Silent Coronary Occlusion. Painless coronary occlusion may occur, under circumstances which are unpredictable, in patients who have not had prior known heart or circulatory disease. The cause, however, is usually an atherosclerosis of the coronary arteries. Although the attack does not cause pain, it seems that these patients have difficulty in swallowing, and are subject to choking, gagging and, some of them, dyspnea These manifestations may be considered as equivalents of pain

Hypertensive Arteriosclerotic Heart Disease. Hypertension, arteriosclerosis, atherosclerosis and hypertensive heart disease may be related to bodily build and constitution These may be more frequently present in the obese and occur with some predilection for the short, short-necked, stocky individual But are not short, stocky individuals predominant in the general population?

Hypertension, arteriosclerosis and atherosclerosis are uncommon before the age of 20 years Before the age of 20 years hypertension occurs chiefly with coarctation of the aorta, with acute or chronic glomerulonephritis, and rarely with endocrine tumors Thereafter it is encountered in 20 to 25 per cent of the general population and in 40 to 60 per cent of those more than the age of 50 years.

Atherosclerosis occurring before the age of 20 years is usually associated with diabetes mellitus or xanthomatosis of the congenital variety or a combination of diabetes and xanthomatosis. Atherosclerosis in the youth may or may not be asso- [illegible]

C[illegible] Disease. In hypertensive heart disease [illegible] doing its work (compensated), or it is [illegible] Unless increased or excessive demands are made on the heart in compensated hypertensive heart disease, symptoms may long be delayed When symptoms do make their appearance, they are those of left ventricular heart failure.

In the compensated stage of hypertensive heart disease the left ventricle is enlarged. Left ventricular hypertrophy is suggested by a forceful apical impulse, due partly to rotation of the apex nearer the thoracic wall and partly to a more forceful systolic contraction. The second aortic sound is accentuated Compensated hypertensive heart disease does not, in itself, cause murmurs, but an apical or basal systolic murmur may be caused by mitral or aortic sclerosis and calcification In elderly patients who have severe hypertension and pronounced dilatation of the ascending aorta, so-called arteriosclerotic aortic diastolic murmur is heard occasionally.

Elongation of the aorta as it loses its elasticity, attended by palpable pulsations in the episternal notch, with concomitant elevation of the subclavian, carotid and innominate arteries gives rise to strong arterial pulsations in the neck The carotid arteries are occasionally distorted and kinked in such a manner as to produce localized pulsating bulges which may resemble an aneurysm. A congenitally long carotid artery may cause a comparable pulsation

Increased pulsation of the aorta is common in hypertension In cases of longstanding hypertension and aortic arteriosclerosis, elongation and elevation of the aortic shadow are frequently observed roentgenoscopically.

In one fourth to one half of those who have moderate hypertension or arteriosclerosis or a combination of these conditions the electrocardiogram reveals no abnormality Often there is only a left axis [illegible]

[illegible] [illegible] [illegible]pensation in the hypertensive heart is almost always associated with advancing coronary arteriosclerosis Heart failure involves the left ventricle, but later there is evidence of congestion in the systemic circulation as well as in the pulmonary circulation

The hypertensive individual is characterized as a hyperreactor with exaggerated response to various influences, such as cold and epinephrine.

PATHOLOGY In hypertensive heart disease there is hypertrophy of the left ventricle When heart failure comes to those who have hypertension, there are present both dilatation and hypertrophy The left ventricle is primarily affected. The right chambers too may be dilated and hypertrophied as right heart failure is inevitable and when it develops it persists

Coronary arteriosclerosis with or without severe narrowing and with or without occlusion and infarction may be present, and may be the immediate cause of heart failure in hypertension Ischemic necrosis occurs in the hearts of those who have malignant hypertension

It is during the stage of acute heart failure that pronounced cardiac enlargement occurs A systolic murmur if present is often due to functional mitral insufficiency. Gallop (3 1) rhythms and pulsus alternans are common With pulmonary congestion the second pulmonic sound may be louder than the second aortic sound despite systemic arterial hypertension. Auricular fibrillation occurs in 1 of every 4 of those who have hypertensive heart disease Frequently it seems to precipitate heart failure.

The lungs contain water, and there is often edema of the dependent parts.

The combination of diastolic hypertension and left ventricular hypertrophy together with evidence of angina pectoris or coronary occlusion and myocardial infarction, and congestive heart failure or electrocardiographic signs of intraventricular conduction disturbances, or both, should permit of a diagnosis of hypertensive and arteriosclerotic heart disease if aortic stenosis is excluded.

Survival for 10 to 20 years and even 30 years is not unusual In the malignant phase of hypertension, characterized by diastolic pressure of 130 mm. of mercury or more, neuroretinitis and progressive renal insufficiency, the prognosis is grave

THE ENDOCARDIUM

Endocarditis. The term endocarditis is used with the appropriate adjective (bacterial, viral, spirochetal, rickettsial or mycotic) in connection with diseases of the endocardium due to a known causative organism. The term nonbacterial endocarditis designates an endocarditis usually associated with rheumatic fever or some general disease, perhaps the result of a bacterial sensitization reaction, such as rheumatic endocarditis and the endocarditis of Libman-Sacks Nonbacterial thrombotic endocarditis occurs in terminal or cachectic conditions Degenerative alterations of the endocardium are common These include endocardial sclerosis, calcification, ossification, fatty degeneration, and amyloidosis

The presence of superficial excrescences, verrucae, on the surface of the valvular or occasionally on the parietal endocardium, is the obvious feature of an endocarditis Valvular endocarditis may occur without the formation of verrucae, or verrucae may be present on one or more of the valves while other valves are free

Acute Bacterial Endocarditis. Bacterial endocarditis occurs in acute and subacute forms The acute forms of disease are mentioned in association with descriptions of the causative organisms. The disease occurs when there is bacterial invasion of the blood stream, with localization of the bacteria on the endocardium Once the bacteria are seated on the endocardium, there are persistent bacteremia, toxemia and embolization due to the bacterial vegetations breaking away from the endocardium Acute bacterial endocarditis is characterized by having been preceded by a local or a general infection Many of these patients have had previous endocardial disease Many of them, too, have normal hearts at the beginning of the acute endocarditis.

Acute bacterial endocarditis is commonly due to hemolytic streptococci, pneumococci or *Staphylococcus aureus*. The hemolytic streptococci belong serologically to Lancefield's group A, but occasional instances due to streptococci of group C or B subsequent

to abortion or delivery occur. Pneumococci responsible for acute bacterial endocarditis are usually aerobic but may be anaerobic.

Among a variety of other organisms responsible for acute bacterial endocarditis are *Neisseria gonorrhoeae*, *Neisseria meningitidis*, *Escherichia coli*, *Pseudomonas aeruginosa* (*Bacillus pyocyaneus*), *Klebsiella pneumoniae* (Friedlander's bacillus), *Actinomyces bovis*, *Micrococcus rugatus*, spirilla and *Bacillus anthracis* Many of this latter group may produce either an acute or a subacute bacterial endocarditis

Age, sex and race do not appear to be significant predisposing factors

In acute bacterial endocarditis the vegetations may be superimposed on thickened, scarred, vascularized, rheumatic valves or on congenital cardiac lesions or they may be on valves with little, minimal or no previous deformity. The pneumococcal and gonococcal infections often occur on previously normal valves and they affect the aortic valve more frequently than do the other organisms. Vegetations on the right side of the heart are caused most often by the gonococcus.

Ulceration is a feature of the acute form of the disease, valvular destruction being especially severe in the pneumococcal and gonococcal infections. The interventricular septum and rarely the cardiac wall may be perforated An accompanying pericarditis is a common finding.

The *spleen* is enlarged and may contain small abscesses. The *liver* may disclose focal or diffuse areas of necrosis and degeneration. The *kidneys* often present hemorrhages, infarcts and sometimes small or large abscesses One large abscess, renal carbuncle, may occur in staphylococcal septicemia Multiple renal abscesses are characteristic of this septicemia There may be a focal or acute diffuse glomerulonephritis The *eye* may be affected by panophthalmitis, but more commonly there is simply a choroiditis

The general symptoms are those of the primary infection which has originated the bacteremia During the course of such an infection a chill and fever may signify the beginning of the septicemia The fever then persists despite the disappearance of the original focus of infection which seems to have healed In other instances, during the course of an infection, there are chills, profuse sweats, marked weakness and various cerebral and psychic disturbances, embolic and vascular symptoms consisting of vascular occlusions in parenchymatous organs, or in the extremities, and cutaneous lesions The vascular occlusions may affect the brain, producing hemiplegia There may be occlusion of peripheral arteries Pulmonary infarctions causing hemoptysis are common All of these complications give their respective localizing symptoms

On examination cutaneous manifestations consisting of petechiae, hemorrhages, and erythematous, bullous and purulent lesions may be evident The spleen may be palpable The other physical findings are those of the original focus of infection This focus may not be evident

The heart rarely contains any physical abnormalities which are of significance There may be a systolic murmur or an increase in intensity of one which may have been present. There are a rapidly developing anemia, a leukocytosis and perhaps a positive blood culture

In acute bacterial endocarditis the culture of organisms from the blood stream confirms only the diagnosis of a bacteremia. The appearance of successive generations of white-centered cutaneous petechiae in a patient who has a proved bacteremia is very suggestive that the endocardium is likewise affected If on ophthalmoscopic examination petechiae are present in the choroid or if a panophthalmos develops, acute bacterial endocarditis is a likely diagnosis

Subacute Bacterial Endocarditis. In 9 of every 10 who have subacute bacterial endocarditis the causative organism is a nonhemolytic streptococcus. The causative organisms in the rest of those who have subacute bacterial endocarditis comprise a great variety of microorganisms. Almost any organism capable of producing septicemia may cause subacute bacterial endocarditis

Subacute bacterial endocarditis almost always affects a heart which has valvular defects, usually acquired from an earlier rheumatic fever A few patients in the

younger age groups have congenital cardiovascular anomalies which predispose to subacute bacterial endocarditis

Subacute bacterial endocarditis often develops after some inconsequential event such as the extraction of a tooth or the removal of tonsils, or a bad cold, especially in those who have rheumatic or congenital cardiac valvular defects.

The highest incidence of this disease is from 20 through 29 years of age, but subacute bacterial endocarditis may occur at any age from early childhood to late in life. There is a somewhat higher incidence among men than among women

PATHOLOGY. The vegetations are usually situated on the leaflets of the mitral valve but may affect any or all of the valves.

The myocardial lesions consist of small infarctions, bacterial embolization of arterioles and capillaries, necrosis of the walls of these small vessels, and surrounding inflammatory reactions

In subacute bacterial endocarditis often the *kidneys* may present diffuse petechial hemorrhages which produce depressed, yellowish, sharply demarcated lesions of the cortex indicating the sites of infarction The *spleen* is almost invariably enlarged and contains infarcts

Lesions of the *brain* are frequent and widespread. There is often a diffuse meningoencephalitis due to disseminated bacterial embolization of arterioles and capillaries Embolic lesions of the large cerebral arteries are common and in some cases prove fatal Bacterial emboli lead to mycotic aneurysms and thrombosis Cerebral, intraventricular or subarachnoid hemorrhage may result from rupture of a mycotic aneurysm Encephalomalacia is a consequence of vascular (embolic) occlusion Occasionally small or large cerebral abscesses are formed

In the lungs congestion, pulmonary emboli and infarctions, and bronchopneumonia may be present The liver is enlarged and engorged owing to chronic passive congestion The stomach and the intestines almost always are involved during the course of subacute bacterial endocarditis, the involvement originates from embolic phenomena Bacterial emboli also affect the large or small arteries of the extremities causing circulatory disturbances and, in some, gangrene

SYMPTOMS The symptoms of subacute bacterial endocarditis are referable to the general infection, to the embolic and vascular phenomena and to the affected heart The onset is usually insidious It may commence acutely, however, with chills and high fever An acute onset is generally due to embolus in a cerebral, an abdominal or a peripheral vessel

At the onset fever is the most constant of all symptoms It may be continuous, remittent, intermittent or septic The temperature is rarely more than 103 F (39 4 C), the usual range is between 100 and 102 F (37 7 and 38 8 C) Periods of apyrexia lasting for weeks at a time often supervene Shaking chills or chilly sensations are common During the chill the temperature is likely to reach 104 to 105 F (40 to 40 5 C) with quick rise and sudden fall of the temperature Profuse night sweats, even in the absence of known fever, are common Pallor, weakness, headaches, tenderness over the long bones and the sternum, breathlessness and easy fatigability are common subjects for complaint

Anorexia, abdominal pain, nausea and vomiting are common and diarrhea may be severe For weeks in the beginning of the disease, diarrhea and fever may be the only symptoms

Splenic infarction may be characterized by sharp sudden pain in the left side of the hypochondrium or the lower part of the left axilla which may extend to the left shoulder or precordium. There may be local soreness and hypersensitivity of the skin over the splenic region

Cerebral or spinal cord infarction may be manifest by the sudden occurrence of hemiplegia or monoplegia In the symptomatology of subacute bacterial endocarditis it is well to be aware that many of the emboli reach small arteries and cause localized symptoms more frequently than they reach the arteries to vital organs and produce alarming symptoms.

Examination. The *skin* is pale and often there are petechiae. The petechiae are most frequently and best observed in the conjunctiva, especially of the lower lid, in the oral mucosa and on the soft and hard palates, in the fundus, in the skin about the clavicles and in the lower extremities Some petechiae may have white centers Petechiae occur in successive generations. Each generation disappears after several days, to be succeeded by another at some future date.

Tender cutaneous lesions which are raised, swollen patches from a few millimeters to 0.5 cm in diameter, bluish, or pink or red, occur in the pads of the fingers or toes, in the thenar or hypothenar eminences, on the soles of the feet, or between the toes These lesions are always tender. It seems that these tender nodes when present are pathognomonic of subacute bacterial endocarditis.

The cardiac findings are those of the existing valvular disease or congenital malformation. In the beginning of subacute bacterial endocarditis valvular lesions may be present of which the patient is unaware As the heart is repeatedly examined during the progress of the disease, there are changes in the character and sites of murmurs, or new murmurs develop. A new murmur, rough in tone, which appears suddenly may be due to rupture of a chorda tendinea or perforation of a valve cusp.

Jaundice may be present and the liver may or may not be palpable The jaundice may be associated with pulmonary infarction or with gonorrheal endocarditis. The spleen is palpable in at least two thirds of those who have subacute bacterial endocarditis

Clubbing of the fingers and of the toes is frequent

Sudden blindness and ophthalmitis may result from embolism of the central retinal artery Visual field defects and fever when of sudden onset may be suspected as being the result of subacute bacterial endocarditis Retinal hemorrhages may be present (see Diseases of the Eye, Chapter 4)

Anemia is a common feature of the disease Leukocytosis is not characteristically present unless there is some complication The sedimentation rate of erythrocytes seems to be accelerated in subacute bacterial endocarditis Polymorphonuclear leukocytosis is slight if present at all Blood cultures are found to be positive in 9 of 10 who have the disease. Cultures may have to be repeated before positive ones are obtained

The urine may contain blood and albumin especially after infarctions of the kidneys There may be a focal glomerulonephritis present

Diagnosis The diagnosis of subacute bacterial endocarditis is based on the presence of (1) a positive blood culture, (2) embolic phenomena, (3) a febrile course and (4) a valvular defect or congenital cardiovascular lesion The diagnosis of subacute bacterial endocarditis should be assumed as most probable whenever a patient who has an organic cardiac murmur experiences fever, without apparent cause, for more than one week

Blood cultures have acquired additional importance above that of diagnosis because beneficial treatment is most likely when the causative organism is identified and its sensitivity to individual antibiotics is determined

VALVULAR HEART DISEASE

There are two types of valves in the heart the bicuspid (mitral) and the tricuspid between the atria (auricles) and the ventricles, and the two sets of semilunar valves at the entrance of the pulmonary artery and aorta

The *bicuspid* or *mitral valve* is the most important and the most deeply seated It is situated under the edge of the left border of the sternum opposite the fourth costal cartilage It separates the left atrium and ventricle and lies nearly transversely

The *tricuspid valve* is situated under the middle of the sternum opposite the fourth intercostal space It runs obliquely downward and to the right from the third left intercostal space to the fifth right costal cartilage. It separates the right atrium and ventricle

The *pulmonary semilunar valve* lies opposite the sternal end of the third left costal cartilage. It is the most superficial valve and the one highest up on the sternum It prevents regurgitation of the blood into the right ventricle from the lungs

The *aortic semilunar valve* is situated under the left side of the sternum about level with the lower edge of the third costal cartilage.

Mitral Valvular Disease. Rheumatic endocarditis of rheumatic fever is responsible for almost all mitral valvular disease Mitral valvular disease occurs as (1) mitral insufficiency and (2) mitral stenosis

Mitral Insufficiency. This form of disease occurs as the result of imperfect closure of the valves The disease is called also organic mitral insufficiency and relative mitral insufficiency

In rheumatic fever there is first an organic mitral insufficiency Other causes for organic mitral insufficiency are bacterial endocarditis, traumatic rupture of a cusp or of the chordae tendineae, spontaneous rupture of the chordae, and rupture of a papillary muscle

Organic mitral insufficiency is consequent to incomplete closure of the mitral orifice which results from imperfect coaptation of the valve cusps because of scarring, thickening, shortening and deformity In others there are fusion and shortening of the chordae which fix the cusps and restrain their apposition so as to prevent closure of the valvular orifice In still others there exist inflammation and scarring of the mitral ring which dilate the orifice and interfere with the muscular systolic shrinkage in the size of the ring.

Rupture of the mitral valve may cause mitral insufficiency by perforation or tear of a cusp or by rupture of chordae or a papillary muscle Spontaneous rupture of chordae tendineae, usually of previously diseased valves, may occur.

Relative or functional mitral insufficiency occurs commonly as a result of great dilatation of the left ventricle in association with left ventricular failure. Imperfect valvular closure under such circumstances is due to dilatation of the mitral ring and to retraction of the cusps by the chordae and papillary muscles Relative or organic mitral insufficiency may be caused by any of the etiologic causes of heart failure; these are mainly rheumatic fever and arteriosclerosis.

The left atrium dilates and hypertrophies in both mitral insufficiency and mitral stenosis It may attain a volume of 2 or 3 liters In contrast, an advanced mitral stenosis may be present without atrial enlargement if the heart is generally enlarged

In hearts with predominant mitral stenosis the left ventricle is of normal size, or may be smaller than normal, or atrophic

Symptoms Many patients who have mitral insufficiency enjoy a normal life Compensation of mitral insufficiency is effected by dilatation and hypertrophy of both the left atrium and the left ventricle When symptoms appear, they are those of congestive heart failure

Examination On physical examination there may be only a loud, harsh or blowing systolic murmur near the apex, with varying degrees of transmission toward the axilla. A murmur which is not transmitted to the axilla is usually indistinguishable from insignificant functional murmurs

If roentgenoscopic examination reveals an enlargement of the left atrium and the left ventricle, the significance of the murmur is thus assured

If there is a rupture of the mitral chordae tendineae, the systolic murmur is loud and is associated with a thrill There may also be an associated apical diastolic murmur

Heart failure resulting from mitral insufficiency is rare. If heart failure should be present, it results from an active rheumatic myocarditis or an unusual strain such as may attend gestation.

The electrocardiogram in mitral insufficiency shows a tendency to left axis deviation. The P waves may be tall and notched.

DIAGNOSIS. The diagnosis of mitral insufficiency is based on the presence of an apical systolic murmur and enlargement of the left atrium and ventricle, and usually a history of rheumatic fever or chorea.

The diagnosis of mitral insufficiency due to nonrheumatic causes is based on the sudden development of a loud apical systolic murmur and thrill in the course of bacterial endocarditis or myocardial infarction, after thoracic injury, or after severe exertion

The presence of an apical systolic murmur in a patient who has hypertension or coronary artery disease and heart failure which disappears with improvement of the circulatory status, confirms the functional nature of the disturbance.

Calcification of the mitral cusps almost always occurs in organic rheumatic mitral insufficiency or stenosis.

If there is no more evidence of heart disease than a murmur, there is no certain method of differentiating whether the murmur is organic or functional in origin Functional murmurs are more commonly present than organic murmurs and are the loudest in the pulmonic region, transmit poorly and are faint in intensity. Cardiorespiratory murmurs disappear when the breath is held

Mitral Stenosis. Mitral stenosis is due mainly to rheumatic endocarditis but occasionally it is a congenital defect due either to anomalous development or to fetal endocarditis Rheumatic mitral valvular disease occurs much more frequently among girls and women than among boys and men

In mitral stenosis the mitral orifice is obstructed and too little blood flows from the left atrium into the left ventricle during ventricular diastole and, consequently, into the aorta in ventricular systole Hypertrophy and dilatation of the left atrium develop, and increased pressure in the pulmonary circulation and hypertrophy of the right ventricle ensue The right ventricle dilates when it becomes inadequate for the work required of it

Thrombi arising in the auricles occur at any stage of mitral stenosis, but they are especially frequent after right heart failure and development of atrial fibrillation. In the absence of right heart failure and consequent dilatation of the right atrium, the thrombi are usually confined to the left atrium

Embolization of the kidneys, spleen, hepatic artery, mesenteric artery and peripheral arteries occurs Embolization of the aorta with formation of a thrombus at its bifurcation may cause sudden sharp pain in the abdomen, lower part of the back, and the extremities, loss of pulsation and warmth of the lower extremities, and shock More localized symptoms occur with embolization of the popliteal, femoral or brachial arteries. Gangrene may result Subsequent emboli in other parts of the body may eventually cause death Extensive infarction of the lungs and spleen may occur in which minimal or no recognizable symptoms are present

A sudden hemiplegia may occur in the presence of a well-compensated mitral stenosis Sometimes these hemiplegias are relatively benign in that they clear up with but slight disability, only to be repeated. Occlusion of a small cerebral artery may occur, followed by only a focal paralysis or isolated aphasia

SYMPTOMS Often patients who have mitral stenosis have no cardiac symptoms and do not have a known history of rheumatic fever or chorea There is no manifest evidence of a decrease in the cardiac reserve. A normal life is, and has been, pursued Some of these men and women will be aged, but there is only a minimal degree of arteriosclerosis, such a slight degree that there is not the least suspicion that the cardiac signs are originating from this source.

Some of these patients, however, are not so fortunate, for there comes a time when cardiac compensation is imperfect The lungs become congested and attempts at unusual degrees of bodily exertion result in dyspnea

Mild degrees of disturbance of gaseous exchange in the lungs, for instance, at the stage of left atrial failure, may cause dyspnea and cyanosis A mild degree of cyanosis produces the so-called mitral facies, which is characterized by a cyanotic flush of the skin over the malar prominences and a dusky cyanosis of the lips which is most

evident after exertion Severe degrees of cyanosis are present in long-standing instances of mitral stenosis

Dyspnea on exertion is the commonest complaint of the patient who has mitral stenosis Many patients who have mitral stenosis become so accustomed to a mild degree of chronic dyspnea that they are scarcely aware of its presence.

Palpitation and precordial distress are early and constant symptoms The palpitation is especially disturbing at night; the patient often attributes it to indigestion The onset of auricular fibrillation may be described by the patient as palpitation Fibrillation, however, is usually established and associated with a slow ventricular rate for a long time without the patient's being aware of its presence

A cough worse at night and after physical exertion than at other times may be an annoying symptom Secondary bronchial and pulmonary infections are prone to complicate pulmonary congestion in mitral stenosis and these may be partially responsible for the cough

Hemoptysis may be the initial and only complaint. It may occur suddenly and be of considerable severity Hemoptysis has been attributed to the rupture of small congested vessels in the lungs, to the rupture of varices of the bronchial veins, and to pulmonary embolization and infarction The ultimate prognosis in those who have hemoptysis is poor

Acute pulmonary edema is much less frequent in mitral stenosis than in hypertensive heart disease or in aortic valvular lesions Pulmonary edema follows sudden or severe exertion, surgical operations, pregnancy, childbirth, attacks of paroxysmal tachycardia, or intravenous administration of physiologic saline solution

Angina pectoris when present is due to an associated aortic or coronary artery disease rather than to the mitral stenosis It is rarely present

Paralysis of the left recurrent (laryngeal) nerve may occur as the result of an enlarged left atrium pressing on the nerve The hoarseness may be intermittent at first but may progress to complete aphonia.

Examination In compensated mitral stenosis the pulse is generally normal Fibrillation, extrasystoles and dropped beats are frequent.

Auricular fibrillation is present in about half of those who have mitral stenosis The fibrillation may be paroxysmal at first but becomes persistent It may be an accompaniment of right heart failure or may actually precipitate it However, auricular fibrillation with slow ventricular rate is often compatible with years of comfortable life

The blood pressure in mitral stenosis is usually within normal limits However, a hypertension may be present in some instances.

In children the precordium may bulge Often there are visible pulsations, aside from those of the precordium, in the epigastrium and to the right of the sternum

A late diastolic (presystolic) thrill may be palpated as a vibrating sensation on the surface of the precordium in the region of the apical impulse A palpable shock may accompany the first sound at the apex and the second sound in the pulmonic region The apical impulse is usually felt at its normal site. After experience has been gained, a presumptive diagnosis of mitral stenosis can sometimes be made from palpation alone

The total area of cardiac dullness to percussion is often increased The increase in the area of cardiac dullness is along the left sternal border, at the level of the third interspace and fourth rib. This increase in dullness at the base of the heart is present in both mitral stenosis and insufficiency.

The first sound at the apex is short, loud and booming. A similar booming first sound may be heard in hyperthyroidism

The second sound heard over the pulmonic area is accentuated and may be accompanied by a palpable shock. The pulmonic second sound may be duplicated as well as accentuated.

There is a localized apical diastolic murmur. This may be late in diastole (presystolic), or it may fill most or all of diastole. It may occur in the early or middle period of diastole. The diastolic murmur presumably arises from the noise made by rapid blood flow past the mitral obstruction into the left ventricle. The time in diastole at which this murmur occurs is that at which the pressure difference between the left atrium and the left ventricle is excessive. This pressure difference is accentuated when the left atrium undergoes compensatory dilation and hypertrophy.

The late diastolic (presystolic) murmur in mitral stenosis is of a low tone with a crescendo accentuation merging into an abnormally loud first sound. The murmur is well circumscribed at or near the apex beat This diastolic (presystolic) murmur may be accentuated by a left lateral position, after exercise has quickened the heart rate This murmur is absent until the obstruction of mitral stenosis is significant, and it disappears at the onset of auricular fibrillation and heart failure.

A diastolic murmur (presystolic in time) may be heard in aortic insufficiency, severe anemia, acute nephritis with hypertension, and left heart failure as well as in mitral stenosis

An apical systolic murmur is frequently present owing to significant mitral regurgitation

On occasion a soft-blowing diastolic murmur, known as the Graham Steell murmur, is heard over the pulmonic region. It is probably the result of a functional insufficiency of the pulmonic valve due to pulmonary artery hypertension and consequent dilatation of that vessel and of the pulmonic orifice. The Graham Steell murmur is distinguished from the diastolic murmur of aortic insufficiency by differences in the roentgenologic appearance of the heart and by distinctive peripheral signs.

The roentgenologic appearance of the heart in mitral stenosis varies with the stage or severity of the lesion.

Calcification occurring on the mitral valves or on the annulus fibrosus in the aged is clinically unimportant Calcification of the mitral ring or cusps may be associated with aortic stenosis, also the result of calcification Deposits of calcium may be present in the fibrous septum which in time affects the bundle of His and thus heart block or other disturbances of conduction ensue

In the *electrocardiogram* in mitral stenosis the P waves in leads I and II are often widened and notched, and may be of increased voltage There is usually right axis deviation with evidence of right ventricular strain Occasionally there is evidence of right bundle-branch block. Auricular fibrillation is frequent.

Diagnosis The diagnosis of mitral stenosis is based on a history of rheumatic fever, on the foregoing described physical signs, and on roentgenologic evidence of a large left atrium. The diagnosis is more certain if the characteristic diastolic (presystolic) murmur is heard A sharp, snappy first sound at the apex following the second sound at the apex and a diastolic thrill further support the diagnostic evidence Electrocardiographic records showing right axis deviation, large, notched P waves and auricular fibrillation also suggest mitral stenosis, especially if there is a history of rheumatic fever

Aortic Valvular Disease. *Aortic Insufficiency.* Insufficiency of the aortic valve results from rheumatic fever, syphilis, bacterial endocarditis, trauma, severe hypertension and aortic arteriosclerosis, and dissecting aneurysm of the aorta Aortic insufficiency in patients less than 35 years old is almost exclusively rheumatic in origin and is combined with mitral valvular disease.

Some blood regurgitates from the aorta into the left ventricle during diastole. Since, in diastole, the ventricle also receives its normal amount from the left atrium, its cavity dilates At each systole a large amount of blood is delivered into the aorta, and the wall of the left ventricle hypertrophies.

The heart in aortic insufficiency is very large (oxheart or cor bovinum), weighing

from 500 gm. to 1,000 gm The enlargement involves the left ventricle and interventricular septum

SYMPTOMS If the left ventricle is normal and the mitral valve sufficient, a normal span of life may be expected without symptoms. In those who have compensated aortic insufficiency, the symptoms are often subjective and referable to the forceful ventricular contractions For instance, when the patient lies on the left side, the audible beat of the heart and cervical vessels is disturbing. The conventional crossed legs may be uncomfortable from the pulsating popliteal artery. Vascular pulsation of the uvula may cause an uncomfortable tickling in the throat.

Those who have rheumatic aortic insufficiency may have nocturnal angina pectoris accompanied by a rise in blood pressure, increased pulse and respiratory rate, palpitations, sweating, and flushing of the face In aortic insufficiency of syphilitic origin angina pectoris is often due to the frequency associated stenosis of the coronary ostia or to conventional atheromatous coronary heart disease.

A rapidly developing breathlessness on exertion is the first symptom of left heart failure in aortic insufficiency. The dyspnea may be paroxysmal, appearing suddenly while the patient is at rest as well as during activity. Paroxysmal dyspnea of short duration is characteristic of syphilitic aortic disease Orthopnea is soon added

EXAMINATION The pulse rate is normal in compensated aortic insufficiency. The pulse wave in aortic insufficiency rises and falls rapidly (Corrigan pulse). To find the so-called water-hammer pulse, it is well that the patient's arm be elevated above the head and the pulse palpated in this position

In aortic insufficiency there are marked pulsations in the vessels of the neck, in the temporal arteries and in other large vessels which may impart a to-and-fro motion to the entire head or to the leg when crossed over the opposite knee. Ophthalmoscopic examination reveals pulsations of the retinal arteries as well as of the veins

The capillary pulse may be observed in a normal person when the skin is warm In sickness the phenomenon is observed in fever, anemia, hyperthyroidism, and aortic insufficiency Capillary pulsation may be elicited in several ways: (1) by observing the nail bed or skin at the root of the nail while pressure is made on the tip of the nail, (2) by observing the edge of the blanched region when the mucous membrane of the lip is compressed by a glass slide, (3) by observing the earlobe or finger tip while it is being transilluminated by a weak source of light

The apical impulse is forceful and is situated to the left of and below its normal site It may be seen or felt in the left axilla. A diffuse systolic depression of the anterior thoracic wall, medial to the forceful apical beat, is caused by the wide excursions of the contracting ventricle within the closed thoracic cage

Percussion reveals an enlargement of the heart to the left and downward There is a soft, high-pitched diastolic murmur In syphilitic aortic insufficiency it is often louder and lower-pitched than in the rheumatic form of the disease. In traumatic aortic insufficiency the murmur is often extremely loud and has a pleasant quality It starts immediately after the second sound It is best heard in the second right intercostal space or along the left border of the sternum in the third or fourth interspace

A low diastolic blood pressure is regularly present in aortic insufficiency (60 mm. of mercury or lower) The systolic pressure is normal or increased and thus the pulse pressure is increased.

The diastolic murmur of aortic insufficiency is often a difficult heart murmur to hear. In searching for the murmur, ask the patient to stand, to bend slightly forward or assume the crawling position, and hold the breath intermittently during auscultation. A systolic murmur situated at the base of the heart when present may be helpful for purposes of timing the murmurs.

A late diastolic apical murmur (Austin Flint murmur) occasionally is heard in aortic insufficiency when there is left ventricular failure. This murmur is identical with the late diastolic (presystolic) murmur of mitral stenosis The mitral valve is normal, however, in those who have an Austin Flint murmur.

On auscultation over the femoral artery a booming sound synchronous with each pulse through the vessel may be heard. This sound has been described as resembling a pistol shot. In some instances a double sound (Traube's double tone) is heard in aortic insufficiency instead of the single pistol-shot sound.

A systolic murmur is present over the femoral artery in normal persons if the vessel is slightly compressed by the bell of the stethoscope In aortic insufficiency a diastolic as well as a systolic murmur is audible over the compressed vessel because there is a rapid diastolic regurgitation toward the heart as well as systolic forward passage toward the periphery This double murmur (Duroziez's sign) is not limited to aortic insufficiency but may also be present in hyperthyroidism, febrile states and anemia.

Diagnosis A diagnosis of aortic insufficiency can be made when there are enlargement of the left ventricle, a high-pitched but often scarcely audible diastolic murmur over the aortic region or along the left border of the sternum, and when present, peripheral circulatory phenomena There is an increased pulse pressure obtained by use of the sphygmomanometer.

Cardiac failure is an integral part of the course of aortic insufficiency, and there may be no significant symptoms before failure occurs Sudden death is frequent in this form of valvular heart disease

Aortic Stenosis. Rheumatic fever is the chief cause of aortic stenosis before the age of 50 years Aortic stenosis after the age of 50 years results from atherosclerosis

The heart in all forms of aortic stenosis is hypertrophied In the smaller hearts the hypertrophy is confined to the left ventricle In the larger hearts dilatation and hypertrophy involve the right ventricle as well as the left ventricle, and often the atria.

Complete heart block, bundle-branch block, intraventricular conduction defects and delayed auriculoventricular conduction frequently are present and result from an extension of the calcific process from the aortic valve to the fibrous septum

Symptoms Compensated aortic stenosis is asymptomatic When valvular obstruction develops then symptoms commence.

Cardiac pain is present in 1 or 2 of every 10 who have aortic stenosis Angina pectoris is more frequently suffered by those who have aortic stenosis than by those who have other valvular heart lesions

Dizziness, faintness and syncope associated with exertion or change of position may be the subject of complaint Convulsive disorders may occur as a part of the symptom complex of aortic insufficiency

Dyspnea on exertion is the first symptom of left heart failure in aortic stenosis. It may be present for months or even a year or two before the other symptoms commence In time nocturnal paroxysmal dyspnea (cardiac asthma) supervenes. Insomnia, nightmares, cough and expectoration, occasional hemoptysis, and orthopnea are symptoms of heart failure and are common in aortic stenosis

Examination The pulse in advanced aortic stenosis is of small amplitude, rises slowly and falls away slowly (pulsus parvus et tardus) Its slow maintained elevation imparts to it the form of a plateau. There is a delay in arrival of this slow small pulse at the wrist.

The blood pressure in aortic stenosis may be within normal limits The systolic pressure may be slightly diminished, and the diastolic slightly elevated, with a resultant small pulse pressure, even though these pressures are still within the range of the normal limits The systolic pressure on the average is increased

Palpation often reveals a systolic thrill at the base of the heart, to the right of

the sternum or along the right cervical vessels. This thrill is best felt if the patient sits or stands and bends forward.

Over the aortic region there is a loud, long systolic murmur which is rough in quality and is transmitted to the neck and to the left axilla The murmur may be heard downward along the sternum toward the apex and occasionally in the left infrascapular region in the back. A diastolic murmur over the base of the heart often is present

The second sound over the aortic area is normal or is heard with difficulty or it is absent.

The presence of effusions in the serous cavities, particularly hydrothorax, cyanosis, weakness, loss of weight and emaciation, portend an impending disaster. Sudden death is common in this disease

Roentgenologic examination reveals that in size the heart is either normal or diminished

The electrocardiogram may reveal normal conditions or may show only a left axis deviation if there is no associated mitral stenosis However, there may be permanent or transient conduction disturbances and abnormalities of the T waves and RS-T transitions

DIAGNOSIS In aortic stenosis a loud, rough, aortic systolic murmur, an aortic systolic thrill, absent or faint second aortic sound and a small, delayed pulse suffice to justify the diagnosis The finding of calcification of the aortic valves on roentgenologic examination is confirmatory In the presence of mitral stenosis the diagnosis is often impossible to make.

Those who have a calcific form of the disease have a good prognosis The outlook remains favorable so long as compensation is maintained Heart failure is usually fatal in this disease

Tricuspid Valvular Disease. Organic tricuspid insufficiency is generally caused by rheumatic fever In some instances it may result from trauma or congenital malformation. Occasionally a functional tricuspid stenosis originates from bacterial vegetations or thrombi Still more rarely tumors projecting into the tricuspid orifice cause an insufficiency The tumors may be primary myxoma or sarcoma or secondary metastatic lesions of hypernephroma, sarcoma of the testis, carcinoma of the thyroid or other neoplasms

The usual age of incidence is between 25 years and 40 years, but occasionally the disease is present in persons more than 50 years of age Women are more commonly affected than men

Tricuspid insufficiency and stenosis are usually a part of rheumatic fever The right ventricle may be normal in size or only slightly hypertrophied but usually it is both dilated and hypertrophied The venae cavae are dilated Systemic venous distention occurs early The liver, spleen and kidneys reveal chronic passive congestion Cardiac cirrhosis of the liver is frequent

The dynamics of tricuspid lesions may be modified and are often dominated by those of an associated mitral or aortic valvular disease.

SYMPTOMS The symptoms of tricuspid valvular disease are those of right-sided heart failure with systemic venous engorgement.

EXAMINATION On examination there is cyanosis which is more pronounced in those who have tricuspid and mitral stenosis combined than in patients who have mitral stenosis alone Jaundice may be present

In tricuspid insufficiency the negative venous wave is replaced by the so-called positive venous pulse This positive venous pulse is often visible as a broad systolic wave ascending the neck along the course of the internal jugular vein up to the ear

In tricuspid insufficiency there is usually a palpable pulsation of the liver during ventricular systole. The systolic hepatic pulse is elicited as an expansile sensation when one palm is held over the posterolateral surface and the other anteriorly over

the liver. Practice is required to attain sufficient skill to elicit this pulse. Hepatic enlargement is constant. There often is ascites.

In primary tricuspid stenosis and in tricuspid insufficiency peripheral edema may be absent. In cases of functional tricuspid insufficiency edema may be absent but it is usually present

Percussion reveals an enlarged heart The right border may reach the right midclavicular line indicating a constant and definite cardiac enlargement.

The findings revealed by examination in tricuspid valvular disease are often determined by the associated mitral stenosis or other valvular disease When tricuspid insufficiency is manifest, there may be a reverberatory movement of the thoracic wall due to a pulsating liver, and ventricular systoles.

The tricuspid lesion may produce a systolic murmur over the lower end of the sternum or adjacent to it. This murmur is indistinguishable from a mitral murmur. When tricuspid stenosis is present a diastolic murmur may be heard which may be accompanied by a thrill However, these findings are usually those of mitral stenosis or of mitral and aortic disease.

The electrocardiogram reveals a right axis deviation and inversion of the T wave in lead III and often also of the T wave in lead II. There may be wide, notched and high voltage P waves when there is sinus rhythm. Auricular fibrillation is common

Diagnosis. The presence of systemic venous congestion, cyanosis, ascites and valvular heart disease is sufficient for a presumptive diagnosis of tricuspid heart disease The roentgenogram reveals clear lungs and enlargement of the right atrium.

Functional tricuspid insufficiency often signifies the end stage of chronic valvular heart disease or pulmonary disease and therefore is always serious.

Differentiation of tricuspid valvular heart disease from constrictive pericarditis is difficult In constrictive pericarditis the heart is not enlarged and evidence of organic cardiovalvular disease is absent

Organic tricuspid valvular disease may be compatible with life for a long period during which the only discomforts, if any, result from venous engorgement punctuated by recurring ascites.

Pulmonic Valvular Disease. Pulmonary insufficiency is classified as congenital and acquired A clinical separation of these two classes of pulmonary valve lesions frequently cannot be made in the adult.

Functional or relative pulmonic insufficiency occurs as the result of a high pressure in the pulmonary artery. The commonest cause of organic pulmonary insufficiency is pulmonary emphysema and rarely bacterial endocarditis involving the pulmonic valve. Bacterial endocarditis of the pulmonic valve is usually not accompanied by other valvular lesions

In pulmonic insufficiency there is dilatation of the pulmonary artery, hypertrophy of the right ventricle with regurgitation of blood from the pulmonary artery

The symptoms of pulmonic insufficiency are always dominated by those of the primary disease Dyspnea and cyanosis may be intense. Polycythemia is observed in the cyanotic patients, and hemoptysis is frequent.

Examination reveals the findings of the primary disease. There may be a Graham Steell murmur in the second or third left interspace in the presence of mitral stenosis and accentuation of the second pulmonic sound

Roentgenologic examination discloses evidence of right ventricular hypertrophy and often a dilatation of the pulmonary artery.

The diagnosis is rarely made clinically.

Cor Pulmonale. Hypertrophy of the right ventricle of the heart, or cor pulmonale, occurs in acute, subacute or chronic form The acute form is commonly caused by large pulmonary emboli The subacute form frequently is due to metastatic carcinomatous infiltration of the perivascular lymphatics and of the pulmonary arterioles; occasionally the subacute lesion follows embolism of the smaller pulmonary vessels. Similar changes in the right ventricle have been found in sickle cell anemia attended by multiple dissemi-

nated thromboses of the smaller pulmonary arteries. Chronic cor pulmonale is often associated with enlargement of the right side of the heart in association with chronic obstructive emphysema, silicosis, bronchiectasis, tuberculosis, bronchial asthma, silicotuberculosis, kyphoscoliosis and pulmonary arteriolar sclerosis In silicosis and bronchiectasis cor pulmonale occurs oftenest in association with peribronchial and perivascular fibrosis rather than with the nodular fibroses In tuberculosis the changes in the right ventricle usually follow extensive sclerotic lesions in the lungs Thoracic deformities, kyphoscoliosis and secondary emphysema seem to be factors in the production of pulmonary hypertension and hypertrophy of the right ventricle. Pressure by tumor on the main pulmonary artery, organized vascular thrombi, schistosomiasis with parasitic invasion of the walls of the pulmonary vessels and diminution in the caliber of the vascular channels lead to increased resistance to the flow of blood and hypertrophy of the right ventricle

A congenital or acquired cardiac lesion with arteriovenous fistulae may cause pulmonary congestion and hypertension

Cor Pulmonale Due to Pulmonary Emphysema (*Emphysema Heart*). Arteriosclerotic changes in the larger pulmonary arteries as well as in the small arteries and arterioles of patients who have advanced emphysema are more frequent and more severe than in normal persons of similar age

Advanced pulmonary emphysema with considerable arterial oxygen unsaturation requires a greater cardiac output In response to the anoxemic stimulus to the bone marrow there is a development of polycythemia, which is an attempt to restore the normal hemoglobin content of oxygen despite the diminution in percentage of oxygen saturation

When virulent bronchopulmonary infection complicates pulmonary emphysema, there is inadequate oxygenation of tissue and right ventricular strain and failure ensue. Bronchial asthma causes cor pulmonale indirectly by first producing an obstructive emphysema Pulmonary tuberculosis of an advanced degree, like obstructive emphysema, may produce both right ventricular hypertrophy and congestive heart failure.

Hypertrophy and dilatation of the right ventricle are present in those who have severe kyphoscoliosis The significant type of kyphoscoliosis is situated in the lower cervical and upper thoracic regions or in the midthoracic region, with the curvature convex to the right. Men are predominantly affected In most cases the cause of kyphoscoliosis is hereditary and congenital However, tuberculosis of the spinal column, rickets, poliomyelitis and osteoarthritis are the causative agents in a great many cases

In kyphoscoliosis in either the congenital or acquired form the thoracic cavity is shortened, the diaphragm elevated, and the volume of the thoracic cavity and consequently of the lungs is diminished The lung on the side of the deformity is compressed, atelectatic, and eventually becomes fibrotic

Symptoms. Rarely are the symptoms of sufficient distinctiveness to cause more than a suspicion of chronic cor pulmonale. Pulmonary emphysema exists as such with or without complications A progression of the disease is complicated by bronchitis or asthma or both A pulmonary circulatory insufficiency may exist in a compensated stage from the time of inception of the emphysema

During the compensated stage of pulmonary heart disease from emphysema there are symptoms of pulmonary hypertension in addition to those of asthma The exertional dyspnea of emphysema is more marked and there may be dyspnea at rest. Occasionally cyanosis is intense and associated with polycythemia. In the decompensated stage of pulmonary heart disease, dyspnea, cyanosis, fainting, vertigo, somnolence and occasionally precordial pain are present.

Examination Pulmonary hypertension may be suspected from accentuation of the second pulmonic sound, and right ventricular hypertrophy suspected from a prominent impulse in the epigastrium. There may be roentgenologic evidence of dilatation of the pulmonary arteries and of the right ventricle.

When there is a *decompensated stage of pulmonary heart disease*, the dyspnea

and cyanosis are intensified Associated with intense cyanosis are polycythemia, hepatic enlargement, systemic venous congestion and peripheral edema Peripheral edema and occasionally ascites are present

The circulation time is normal in uncomplicated pulmonary emphysema, even during an attack of bronchial asthma, and it remains normal during the compensated stage of chronic cor pulmonale When intrapleural pressure is increased so is the venous pressure

The electrocardiogram of chronic cor pulmonale may not disclose any abnormality, or it may reveal the changes due to a vertical position of the heart, depression of the diaphragm and right ventricular strain.

DIAGNOSIS The diagnosis of pulmonary heart disease is more definite when right-sided heart failure is associated with primary pulmonary disease. Hepatic enlargement and subcutaneous edema in addition to elevation in venous pressure are indicative of right ventricular failure.

The history and the results of physical and roentgenologic examinations of the thorax will usually reveal the presence and nature of the pulmonary disease and exclude primary cardiovalvular disease The diagnosis of compensated cor pulmonale requires demonstration of right ventricular enlargement indicated by the roentgenologic examination

DISEASES OF THE HEART DUE TO DISTURBANCES OF INNERVATION OR PSYCHIC CONTROL

Neurocirculatory Asthenia or Cardiac Neurosis. This condition is known also as irritable heart, disordered action of the heart, and effort syndrome.

Neurocirculatory asthenia is a syndrome of psychogenic or neurogenic origin simulating organic heart disease, from which it often cannot be differentiated immediately There are complaints of dyspnea, precordial pain, palpitation and exhaustion

These patients often give a history of "nervous breakdowns," indecision, prolonged illnesses and an intolerance for the vicissitudes of daily life This disorder, however, may occur in any person if there is imposed a sufficient amount of exhaustion and emotional trauma

Neurocirculatory asthenia may occur at any age in persons of either sex, but it seems to be commonest in young men, The hereditary and environmental factors may be important A similarity of somatic type of those who have the disorder is often noticeable. They are of an asthenic build with a long and narrow thorax

In some of those who have neurocirculatory asthenia a serious illness has occasioned a long withdrawal from physical exercise Incident to the withdrawal there was time in which anxieties in regard to ultimate recovery seized the patient. With subsequent illnesses the anxiety and prolongation of disability tend to recur In some patients the anxiety will recur in the absence of other illnesses

SYMPTOMS These patients complain of difficulty in breathing, precordial discomfort, palpitation, vertigo, hyperhidrosis, weakness, gastrointestinal disturbances and often headache On questioning, it will be found that they are fearful of some indescribable danger and impending illness In addition to these complaints it will soon be evident these patients are irritable, restless and unable to sleep. There are present anorexia, slowed processes of thought, and feelings of confusion

A characteristic shortening of breath, described as an inability to take a deep breath, occurs while at rest or during exercise The severity of the dyspnea is disproportionate to the degree of exercise and to the objective disturbances in ventilation

Fatigability, a sense of profound fatigue during the early morning hours and, in some, great exhaustion follow physical exertion. A cardiac disorder which confines a patient to rest in bed for 2 or more months without stirring around is usually neurocirculatory asthenia

Spontaneous attacks of dyspnea, deep breathing and tachypnea, often in association with claustrophobia, occur. Excessive hyperventilation causes giddiness or dizziness and sweating and produces tetany.

Pain in the precordium may be a dull, continuous ache or soreness or may be sharp and intermittent The pain is unrelated to exercise. It occurs at any time during or after meals and exertion If the pain occurs during activity, it is not immediately relieved by rest.

Palpitation may be the first symptom There is an awareness of the heart beat actually associated with tachycardia and a forceful cardiac pulsation. Paroxysms of tachycardia are common

EXAMINATION On examination there will be present cold moist hands and feet. The mouth and lips are dry The pulse rate and the blood pressure are variable, but response to graduated exercise tests is normal It is in these patients that exercise tests and occasionally the anoxia test find their most precise diagnostic applicability. There is a general tenseness of musculature, and hyperactive tendon reflexes are present. Tenderness on pressure to the body by the examining thumb will be complained of wherever the thumb applies pressure

Examination of the heart reveals no constant signs of organic heart disease However, the discovery of organic heart disease which has been unknown to the patient may precipitate the symptoms of neurocirculatory asthenia The heart is normal in size The pulse rate is increased

DIAGNOSIS The functional cardiac and circulatory disorder is indicated by the history, and the lack of objective manifestations of cardiac and circulatory dysfunction These objective findings are evaluated, and separately recorded and if there are no history, symptoms and findings other than the cardiac neurosis a diagnosis of neurocirculatory asthenia is made. If there are symptoms and signs of organic heart disease, in addition to those of the cardiac neurosis the proper diagnosis of cardiac disease and neurocirculatory asthenia is made

THE MYOCARDIUM

The Enlarged Heart. Cardiac enlargement is indicative of the presence of cardiac disease. However, an enlarged heart is often found when no definite evidence of disease which has caused the enlargement is demonstrable Confirmation of suspected cardiac enlargement depends on physical and roentgenologic examinations The presence of cardiac enlargement may be suggested or confirmed by the electrocardiographic findings The past history is important.

ETIOLOGY The commonest causes giving rise to enlargement of the heart are hypertension of the essential type and valvular disease of rheumatic or syphilitic origin

Less common causes of cardiac enlargement than hypertension and valvular disease are myocarditis, cardiac infarction, thyrotoxicosis, chronic pulmonary disease, and congenital defects Rare causes are arteriovenous aneurysms, severe anemia, beriberi, hypothyroidism, thoracic and spinal deformities, chronic pericarditis with external adhesions, and cardiac neoplasms Prolonged physical strain, as in athletic sports, and excessive tachycardia and certain arrhythmias may produce some permanent cardiac enlargement Finally, cardiac enlargement may occur from unknown cause

Age Cardiac enlargement may occur at any age In young persons it is almost always the result of acute rheumatic myocarditis or chronic rheumatic valvular disease, in middle age it is due most often to hypertension but also frequently to chronic valvular disease of rheumatic or syphilitic origin and to myocardial infarction, and sometimes to extensive pulmonary fibrosis In old age it is due chiefly to hypertension, to myocardial infarction and pulmonary emphysema

Sex. Cardiac enlargement is common in both sexes, but the largest hearts (aortic regurgitation of syphilitic aortitis) are commoner in men than in women

PATHOLOGY Cardiac enlargement consists usually of hypertrophy of muscle and dilatation of the chambers It may begin as either one and continue preponderantly as hypertrophy or as dilatation.

Hypertrophy consists in the increase in size of the individual muscle fibers and not in their increase in number. Increase in bulk and weight of the myocardium commonly follows considerably increased work if long sustained The heart is made up of masses of muscle continuous between the ventricles and between the auricles respectively, but hypertrophy and enlargement may be limited to a single part (or parts), as in the case of left ventricular hypertrophy in hypertension and of right ventricular hypertrophy in stenosis of the pulmonary valve.

Dilatation of the heart frequently occurs along with hypertrophy as a part of cardiac enlargement. It consists of a stretching of the heart muscle due to a response to excessive physiologic demand for an increased output of blood per beat. Dilatation may persist or increase with continuance of the demand, the tone of the muscle may partly recover but a permanent stretching of the fibers may persist In some instances enlargement of the heart due preponderantly to dilatation may decrease However, this is not the usual experience with cardiac enlargement, which changes little, tending gradually to increase in the course of time

The largest hearts and the heaviest hearts are those in which *hypertrophy* and *dilatation* are associated The heart is so large that it reaches almost to the thoracic wall on the left and considerably more than halfway to the thoracic wall on the right

Examination in Cardiac Enlargement. The evidences of cardiac enlargement are variable and may be inconclusive unless the heart is definitely enlarged The apex beat may be displaced laterally and downward Often cardiac enlargement is present when the maximal apical impulse is situated lateral to the midclavicular line, or more than 4 inches (about 10 cm) from the midsternal line in the fifth left intercostal space, or below the level of the fifth intercostal space Cardiac displacement due to bronchopulmonary lesions may similarly affect the position of the apical impulse In many persons it is difficult or impossible either to see or clearly to feel the apex beat.

An accentuated or diffuse apical impulse may be present in cardiac enlargement. A precordial bulge is often observed in children with cardiac enlargement due to rheumatic or congenital cardiac disease

On percussion of the adult thorax, if cardiac dullness extends beyond 4 inches (about 10 cm) to the left of the midsternal line in the fifth interspace and there is deformity of the thorax, cardiac enlargement is likely to be present. If cardiac dullness extends more than 1⅗ inches (4 cm) from the midsternal line in the third left interspace, there is probably enlargement of the left atrium, dilatation of the pulmonary artery or enlargement of the pulmonary conus of the right ventricle. The accuracy with which the degree of cardiac enlargement can be discovered by percussion is impaired in obese individuals, in those with muscular thoracic walls, in those who have pulmonary emphysema and in women with large breasts Percussion is limited in the accuracy with which the size of the heart can be determined in the normal thorax without any handicaps unless the heart is definitely enlarged However, relatively few of the total number of patients ill with serious heart disease at home can be moved in order to have more refined methods of diagnosis Indeed, these patients should not be moved for study, and under these circumstances the approximations of the size of the heart by physical examination must suffice. It is for this reason that skill in physical examination is helpful

Diagnosis of Enlarged Heart *Roentgenologic Examination of the Heart* Roentgenologic examination of the heart is the most reliable method of determining cardiac enlargement Friedberg has commented that the roentgenologic examination reveals also the volume of the heart and its vascular extensions and the relative size of the individual chambers Rotating the patient enables viewing the heart from different angles

The size of the heart and the presence and localization of cardiac enlargement may be determined by fluoroscopic, orthodiagraphic and teleroentgenographic examinations In special instances, in cases of congenital heart disease and in dis-

tinguishing cardiac enlargement from extracardiac masses, angiocardiographic and electrokymographic examinations may aid in distinguishing cardiac enlargement from pericardial effusion and ventricular aneurysm

The Normal Cardiac Outlines on Roentgenograms Roentgenologists employ three standard views which yield the maximal information as to the shape, size and (by fluoroscopy) the pulsations of the heart. These views are the anteroposterior, the right oblique anterior and the left oblique anterior

In the *anteroposterior view* the *right border* is composed of the contours, which from above downward are, in young individuals, the innominate vein and its continuation into the superior vena cava In older individuals, the ascending aorta may overshadow the superior vena cava In all, the right atrium is the largest salient of the right border of the heart and it comprises the entire right border except for the superior vena cava or the ascending aorta

The *left border* is formed from above downward by the aortic arch continuing into the descending aorta Then follows the pulmonary salient composed of the pulmonary artery and its left main branch. The left ventricle forms the prominent convex contour which curves downward and back toward the midline

The Transverse Diameter The most informative measurement obtained from teleroentgenograms or orthodiagrams is that of the transverse diameter In the erect position of the body the transverse diameter averages between 4 and 5 inches (about 10 and 13 cm) but even greater variations occur normally

The *cardiothoracic ratio* is employed as an index of cardiac enlargement. This is the ratio of the transverse diameter of the heart to the internal diameter of the thorax at its widest point just above the level of the dome of the diaphragm If the cardiothoracic ratio significantly exceeds 50 per cent it is assumed there is cardiac enlargement This is only a rough guide since the relationship varies considerably. Despite the fact that this is only an approximation in practice, it is of great value

The factors which modify the normal cardiac shadow on the roentgenogram are the somatic types For instance, in a short, broad, rounded thorax the cardiac shadow tends to be short, wide and situated transversely, and the apex appears to be displaced to the left The transverse positions of the heart which affect the cardiothoracic ratio and thus suggest left ventricular enlargement result from elevation of the diaphragm, for example, deep expiration In the presence of hepatic enlargement and ascites, during pregnancy and in obese subjects or a stomach distended with gas, the diaphragm and the heart may be displaced upward and the heart thus displaced may appear to be enlarged Scoliosis, even the slight scoliosis commonly seen in children, produces an apparent enlargement of the cardiac shadow if the heart lies to the left of the spinal column A similar effect is produced by widened rib margins in instances of severe rickets A vertical cardiac shadow may occur in the presence of pulmonary emphysema

The Right Anterior Oblique View The patient is rotated anteriorly so that the right shoulder is turned toward the screen The angle formed by the shoulders with the screen should be about 30 to 40 degrees for study of the aorta, 50 to 60 degrees for study of the left atrium The *anterior border* of the cardiac shadow in this position is formed in its upper third by the ascending aorta and arch, and in its lower two thirds by the pulmonary artery and right ventricle The left ventricle forms the lower border on the roentgenogram

The *posterior border* of the cardiovascular shadow, reading from above downward, first is the outline of the right branch of the pulmonary artery and the superior vena cava The descending aorta may be distinguishable The left atrium forms the slightly convex major portion of the posterior cardiac shadow on the roentgenogram The right atrium with the shadow of the inferior vena cava entering it completes the circumference of the posterior cardiac shadow in this position

The Left Anterior Oblique View The patient is rotated anteriorly so that the left shoulder is toward the screen, a position which the right shoulder occupied in the right anterior oblique view. The *anterior border* of the cardiovascular silhouette in this

position, reading from above downward, first is the innominate vein and superior vena cava. The ascending aorta and the right atrium complete the outline

Reading from above downward the upper third of the *dorsal aspect* is formed by the left atrium, and the lower two thirds is the shadow of the left ventricle

Enlargement of the Individual Cardiac Chambers. Advanced enlargement of the heart often involves the entire heart. *Diffuse enlargement of the heart occurs in* various toxic, infectious, and metabolic diseases, for instance, beriberi, severe anemias, and combined left-sided and right-sided heart failure In some of the most important forms of cardiac disease the cardiac enlargement is confined to one or more chambers. Thus the determination of such localized enlargements is of great diagnostic value.

Left Ventricle Early enlargement of the left ventricle is not revealed roentgenoscopically Moderate left ventricular hypertrophy with minimal dilatation, as seen in essential hypertension, is characterized by rounding of the left lower contour of the heart without alteration in cardiac diameters.

In normal individuals apparent enlargement of the left ventricle is usually due to a high diaphragm. Displacement laterally of the left lower cardiac contour may be caused by enlargement of the right ventricle.

Left Atrium Enlargement of the left atrium may cause a straightening of the left border or a prominence situated in the middle of the shadow Often an enlargement of the left atrium is indicated by compression of the esophagus When extreme enlargement of the left atrium is present, the entire right cardiac border is formed by that chamber

Right Ventricle Enlargement of the right ventricle cannot be detected in its early stages. When the right ventricle is greatly enlarged it forms the entire right border of the cardiac shadow.

Right Atrium Enlargement of the right atrium is revealed in the anteroposterior view by lateral displacement of the right lower cardiac shadow beyond the right midclavicular line Enlargement of the right atrium only occurs in generalized cardiac enlargement

Electrocardiographic Evidence of Cardiac Enlargement Alterations in the size and form of the heart alter the form of the electrocardiogram It is desirable, if possible, to differentiate the electrocardiographic changes due to cardiac enlargement from those caused by the position or rotation of the heart within the thorax incident to somatic type of the individual.

The axis deviations in the conventional leads I, II and III have a relationship to the enlargements of the left or the right chambers of the heart The axis deviations are related to the variations of the height or depth of the R and the S waves in the electrocardiogram The higher the R waves are in lead I and the deeper the S waves are in lead III, the greater is the degree of left axis deviation The higher the R waves in lead III and the deeper the S waves in lead I, the greater is the degree of right axis deviation

It is well to realize that left and right ventricular enlargement are common causes of left or right axis deviation, but axis deviations may be observed in the absence of cardiac enlargement Right axis deviation may be observed in a heart with left ventricular enlargement.

The electrocardiogram indicative of left axis deviation may be observed in some asthenic persons who have a transversely situated heart, in the obese, or in those with high diaphragm due to ascites or pregnancy. A deep expiration increases the degree of the left axis deviation in the electrocardiogram

The electrocardiogram indicative of right axis deviation may be present in asthenic persons who have centrally situated vertical or drop heart and in those who have pulmonary emphysema and low diaphragm. A deep inspiration and the upright position increase the degree of the right axis deviation Right axis deviation may

tinguishing cardiac enlargement from extracardiac masses, angiocardiographic and electrokymographic examinations may aid in distinguishing cardiac enlargement from pericardial effusion and ventricular aneurysm

The Normal Cardiac Outlines on Roentgenograms. Roentgenologists employ three standard views which yield the maximal information as to the shape, size and (by fluoroscopy) the pulsations of the heart. These views are the anteroposterior, the right oblique anterior and the left oblique anterior

In the *anteroposterior view* the *right border* is composed of the contours, which from above downward are, in young individuals, the innominate vein and its continuation into the superior vena cava. In older individuals, the ascending aorta may overshadow the superior vena cava In all, the right atrium is the largest salient of the right border of the heart and it comprises the entire right border except for the superior vena cava or the ascending aorta.

The *left border* is formed from above downward by the aortic arch continuing into the descending aorta Then follows the pulmonary salient composed of the pulmonary artery and its left main branch. The left ventricle forms the prominent convex contour which curves downward and back toward the midline

The Transverse Diameter. The most informative measurement obtained from teleroentgenograms or orthodiagrams is that of the transverse diameter. In the erect position of the body the transverse diameter averages between 4 and 5 inches (about 10 and 13 cm) but even greater variations occur normally.

The *cardiothoracic ratio* is employed as an index of cardiac enlargement This is the ratio of the transverse diameter of the heart to the internal diameter of the thorax at its widest point just above the level of the dome of the diaphragm. If the cardiothoracic ratio significantly exceeds 50 per cent it is assumed there is cardiac enlargement This is only a rough guide since the relationship varies considerably Despite the fact that this is only an approximation in practice, it is of great value

The factors which modify the normal cardiac shadow on the roentgenogram are the somatic types For instance, in a short, broad, rounded thorax the cardiac shadow tends to be short, wide and situated transversely, and the apex appears to be displaced to the left The transverse positions of the heart which affect the cardio- [illegible] enlargement result from elevation of

the diaphragm and the heart may be displaced upward and the heart thus displaced may appear to be enlarged. Scoliosis, even the slight scoliosis commonly seen in children, produces an apparent enlargement of the cardiac shadow if the heart lies to the left of the spinal column A similar effect is produced by widened rib margins in instances of severe rickets A vertical cardiac shadow may occur in the presence of pulmonary emphysema

The Right Anterior Oblique View. The patient is rotated anteriorly so that the right shoulder is turned toward the screen The angle formed by the shoulders with the screen should be about 30 to 40 degrees for study of the aorta, 50 to 60 degrees for study of the left atrium. The *anterior border* of the cardiac shadow in this position is formed in its upper third by the ascending aorta and arch, and in its lower two thirds by the pulmonary artery and right ventricle. The left ventricle forms the lower border on the roentgenogram.

The *posterior border* of the cardiovascular shadow, reading from above downward, first is the outline of the right branch of the pulmonary artery and the superior vena cava. The descending aorta may be distinguishable The left atrium forms the slightly convex major portion of the posterior cardiac shadow on the roentgenogram The right atrium with the shadow of the inferior vena cava entering it completes the circumference of the posterior cardiac shadow in this position

The Left Anterior Oblique View. The patient is rotated anteriorly so that the left shoulder is toward the screen, a position which the right shoulder occupied in the right anterior oblique view. The *anterior border* of the cardiovascular silhouette in this

may, like the stroke volume, be reduced but usually to a less degree, since an increase of pulse rate tends to compensate for a decreased output per beat. The erect posture has been found usually to cause a decrease of one fourth to one third of the minute volume calculated for the recumbent position There are other factors which influence blood flow

The normal cardiac output per beat varies in the average adult from 50 to 100 ml. at rest There is an increase of output on exercise which is less in those not accustomed to exercise than it is in those who regularly have physical exercise. In heart failure or extreme tachycardia the cardiac output may be reduced In paroxysmal tachycardia, for example, the cardiac output may be greatly reduced

The speed of flow from arm vein to heart and through heart and lungs to arm artery can be determined The value for this rate of blood flow is termed the circulation rate. Normally this arm to arm circulation time varies from 14 to 24 seconds (average 18 seconds). The arm to arm circulation time increases with the pulse rate but does not change with blood pressure variations, and it is not affected by valvular heart disease The *circulation rate* is decreased in auricular fibrillation and in congestive heart failure. The decrease in congestive heart failure is in accordance with the degree of failure

In the determination of the arm to lung time, that is, the integrity of the venous systemic circulation and the right heart, ether is injected intravenously (using 5 minims of ether and 5 minims of physiologic saline solution); the end point is detected by the patient's consciousness of the presence of ether on the breath. The ether arm to lung time varies from 3 to 9 seconds, averaging 5.8 seconds

In the determination of the circulatory rate, that is, the state of the right ventricle, sodium gluconate, saccharin, or cyanide time (normal average 12 to 15 seconds) is used In the determination of the total heart efficiency, the subtraction of the normal time (12 to 15 seconds) from the time observed in the test will give an estimate of the strength or failure of the left ventricle

Acute Nonspecific Myocarditis. Acute nonspecific myocarditis occurs secondarily to many diseases of bacterial or viral origin and also in some conditions of undetermined origin Acute myocarditis has been demonstrated at necropsy in diphtheria, typhoid fever, paratyphoid fever, typhus fever, dysentery, mumps, pneumonia, scarlet fever, meningococcal infection, gonococcic infection, tularemia, streptococcal and pneumococcal meningitis, pyelitis, bronchiectasis, infectious mononucleosis and acute suppurative tonsillitis

The pathologic change in all instances of acute nonspecific myocarditis is characterized by an acute and often focal inflammation of the myocardium. For instance, in septicemia, a suppurative myocarditis, miliary abscesses may be represented by very small visible spots or streaks surrounded by a red zone which contains pus. The myocardium in rheumatic fever and trichinosis with terminal congestive failure may be diffusely affected [illegible]

SYMPTOMS [illegible]
of the general di[illegible]
fever, or an increase of fever if already present, weakness, palpitation, precordial pain and tachycardia Tachycardia out of proportion to the fever is suggestive of myocarditis if not evidence of peripheral circulatory failure due to toxemia.

Patients whose convalescence from acute infection is slow, with profound asthenia after the acute disease has subsided, may have myocarditis. Slight pre-[illegible]
[illegible] occurring
[illegible] of any
[illegible] of the
heart Enfeeblement of the first heart sound may be the first diagnostic implication of a myocarditis The first heart sound may become indistinguishable from the second sound, resulting in an embryocardiac rhythm An apical systolic murmur occurs frequently A gallop rhythm, with or without cardiac enlargement, occurring in the course of an acute infection, in the absence of pre-existing heart disease, suggests myocarditis

be produced by lateral rotation of the body to the left. A bundle-branch block modifies the apparent electric axis.

The QRS interval may be prolonged to 0.10 or 0.11 second. This prolongation may be due to delay in passage of the electric impulse resulting from an increased thickness of left ventricular muscle or to delay caused by elongation or functional depression of the left bundle branch.

Cardiologists believe that unipolar leads provide more reliable evidence for cardiac enlargement than is obtained by the conventional leads.

Tests of Cardiac Function. Exercise Tests. Before an exercise test is employed, it is well to determine what can be learned from questioning the patient in regard to endurance while performing the ordinary daily activities which are required and have been performed without dyspnea or angina pectoris How long and how far can ordinary walking be pursued without dyspnea or pain? Will it be necessary to hurry, lift or run in order to produce dyspnea or pain? These are but examples of the many inquiries which can be made and which will usually reveal the limits of physical activities which can be indulged in without symptoms Answers to these questions will usually make an exercise test unnecessary

If an exercise test is employed, it should be simple and designed not to exhaust prematurely a person not in good physical training The test or tests are conducted under the observation of the examiner. Walking, marking time by a hopping or running cadence or mounting a specially constructed two step footstool a given number of times within definite time limits are the best tests The test performed with the two step footstool is known as the two step test

In normal persons the blood pressure and pulse return to within 10 of resting levels in one and one-half minutes after a standardized exercise test The more vigorous the exercise, the more slowly do blood pressure and pulse rate return to resting levels In coronary heart disease exercise may cause typical pain

Exercise tests may be of value in detecting coronary insufficiency when it is latent. There is a lag in return of the blood pressure and pulse rate to former levels. The electrocardiogram gives evidence of anoxemia of the heart muscle following exercise ST segment depression or elevation of 1 mm or more in lead I, of 1.5 mm. or more in lead II and lead III and 2 mm. or more in lead IV; and the conversion of T wave in I, II, or IV indicate an insufficient coronary circulation. Likewise the development of bundle branch block is a positive test.

Miscellaneous Tests There are two tests of cardiac function which utilize the respiratory system, namely, determination of vital capacity, and the anoxemia test. The anoxemia test is a special respiratory test which may be of value if performed by those trained to perform it correctly.

The *vital capacity* of the lungs is the measurement, by spirometer, of the amount of air, in liters, that can be expelled by a complete forceful expiration after the fullest possible inspiration (see Diseases of the Lungs, Chapter 9)

There are two primary heart conditions, namely, mitral stenosis and congestive heart failure, which give rise to reductions of vital capacity Pulmonary emphysema, *no matter what may produce it fundamentally*, is also an occasional cause of reduction of the vital capacity

The *anoxemia test* is designed to test the functional capacity of the coronary circulation, especially in persons suspected of having coronary heart disease but without definitely diagnosable angina pectoris or electrocardiographic abnormalities The test is not entirely safe and is less frequently employed than in former times

The determination of the blood flow through the chambers of the heart is dependent on methods utilizing the absorption of such gases as nitrous oxide, ethylene, and ethyl iodide, and acetylene from the lungs in a certain definite time. The time unit is one minute. The volume of *blood expelled from the heart in one minute* which is available to absorb gas is termed the minute volume

The *minute volume* normally ranges from about 3,500 to 9,000 ml (*6 to 12 ml per* [illegible]), being increased by exercise to as high as 20 to 25 liters. It

Electrocardiographic changes may consist of depression of the ST segment and lowering or inversion of T wave, heart block or bundle-branch block.

DIAGNOSIS The presence of acute myocarditis in a patient who has diphtheria is manifested first by a slowing of the pulse There is an enfeebled first sound at the apex, and a gallop rhythm The heart is enlarged. During the second or third week of the disease a severe myocarditis is revealed by the development of congestive heart failure. Electrocardiographic abnormalities consist mainly of a bundle-branch block

Acute myocarditis is a serious complication of diphtheria, accounting for most of the deaths in this disease after the first week

Syphilitic Myocarditis. Primary syphilitic myocarditis is uncommon and is confined to gummatous lesions Gummas situated in the interventricular septum may involve the bundle of His or one of its branches and thus interfere with cardiac rhythm. A gumma may result in cardiac aneurysm, may lead to rupture of a papillary muscle or of the heart wall, or rarely occludes a valvular orifice.

Cardiac gummas and gummatous myocarditis produce no recognizable clinical symptoms Rarely a gummatous aneurysm may perforate into the pericardium and result in sudden death Gummas in the left ventricle or in the interventricular septum may protrude into the valvular regions, producing a pseudostenosis.

Aneurysm of the Ventricle of the Heart. The majority of ventricular aneurysms arise as a result of infarction following coronary thrombosis despite the fact that aneurysms of the heart are uncommon complications of coronary thrombosis

Aneurysm of the ventricle may occur from abscess of the heart wall, from trauma, from ulcerative lesions of bacterial endocarditis or from congenital defects. Instances of the latter type, however, are rare

The left anterior descending coronary artery is the vessel which most commonly is completely occluded, and aneurysms are therefore most commonly present at the apex or anterior wall of the left ventricle These aneurysms are diffuse bulges, varying in diameter from a few centimeters up to a dilatation almost equal in size to the remainder of the ventricle They are rarely saccular in form The overlying pericardium is densely adherent to the heart

SYMPTOMS There is a history of an attack of coronary occlusion The time interval elapsing between this and the development or recognition of the aneurysm is variable, from a few weeks to several years. Occasionally, there is a history of prolonged precordial pain following the initial episode This is not pain of short duration such as occurs in anginal seizures, but is distress lasting for hours or days

EXAMINATION There may be a forceful, abrupt, localized thrust, often felt at or near the apex The heart sounds are enfeebled out of all proportion to the force of the cardiac impulse Gallop rhythm and indistinct murmurs may be present. The blood pressure is commonly normal or low.

Electrocardiograms are of importance only as they may add to the evidence of myocardial infarction and assist in localizing the lesion in the anterior or posterior part of the ventricle

DIAGNOSIS The diagnosis of ventricular aneurysm is based on the clinical history, the physical examination and the roentgenologic study. Roentgenologic study is by far the most important diagnostically

Metabolic and Nutritional Disturbances of the Myocardium. ***Vitamin B_1 Deficiency—Beriberi Heart.*** Beriberi in the United States may be observed in alcoholism and drug addiction, restriction in food intake, neurotic adherence to food fads, poverty with consequent caloric and vitamin deficiency, and occasionally in diabetes, pregnancy and severe gastrointestinal disease.

As part of the *pathologic changes* in beriberi the heart may be normal in size or enlarged Heart failure in beriberi is considered to be the consequence of a thiamine-deficient metabolism of the heart muscle

Acute severe infection associated with toxemia causes peripheral circulatory failure without any significant damage to the myocardium. However, there are alterations of the electrocardiogram which may occur in the course of many acute and occasionally in chronic infectious diseases. These changes are recognized as important in rheumatic disease In the course of acute rheumatic fever or other infections the electrocardiographic changes may return to normal The clinical interpretation is that the pathologic process responsible for the change has resolved without leaving permanent damage to the myocardium.

Congestive heart failure occurs rarely as the result of myocarditis alone. If congestive heart failure occurs during an acute infection, the patient has had a pre-existing heart disease.

DIAGNOSIS The diagnosis of myocarditis can be made correctly and more frequently if it is realized that acute myocarditis is not a rare complication of infectious disease In the experience of Candel and Wheelock clinical evidence of myocarditis was associated with one or more of the following acute infectious diseases peritonsillar abscess, pneumonia, scarlet fever, gonococcic arthritis, cystitis, infectious mononucleosis and typhus fever In addition to the presence of evidence of myocardial strain in a patient who has an acute infectious disease the electrocardiographic alterations may be diagnostically helpful.

Diphtheritic Myocarditis. Acute myocarditis occurs in a few of those who have diphtheria. The incidence is higher in epidemics of severe forms of the disease than in mild forms Myocarditis may complicate cutaneous as well as faucial diphtheria and is often associated with cranial nerve involvement

The circulatory disturbances in those who have diphtheria are due to the action of an exotoxin of the Klebs-Loffler bacillus on the muscle fibers of the heart and vessels. A manifestation of the effects of the exotoxin on the peripheral vessels is the occurrence of shock in some of those who have diphtheria

Fahr described three types of change in the heart. (1) fatty degeneration, (2) myolysis, and (3) interstitial inflammation.

SYMPTOMS. There are both early and late symptoms of acute diphtheritic myocarditis The early symptoms occur near the end of the first week and during the second week In those who have cutaneous diphtheria the heart symptoms may be delayed and begin after 4 to 7 weeks In either instance there are cough and cyanosis which it seems reasonable to attribute to obstruction of the respiratory passages However, those who have a diphtheritic myocarditis, and who have cough and cyanosis, may not have obstruction to the respiratory passages. The cardiac symptoms are often first those of cardiac shock which in rare instances is followed by congestive heart failure

EXAMINATION Tachycardia is usually present in the first week of diphtheria even when there is no demonstrable myocardial involvement. With the development of acute myocarditis there is often a gradual or sharp reduction in the heart rate which may result in a mild or pronounced bradycardia In the third week of the disease tachycardia reappears in those who have myocarditis. Cardiac rates of less than 40 indicate the presence of complete heart block, but the latter may be associated with a normal heart rate or a slight tachycardia Gallop rhythm is an important sign of [illegible] myocarditis with extensive myocardial damage and heart failure Occa- [illegible] nt of the first heart sound, embryo-

Patients who have complete heart block rarely suffer from epileptiform convulsions, syncope or other symptoms of the Adams-Stokes syndrome During the convalescent period, about the fourth to sixth week, patients may present a persistent tachycardia, or a tachycardia induced by slight effort or occurring at the end of the day. A bacterial (diphtheritic) endocarditis due to the Klebs-Löffler bacillus occurs rarely.

Subjective symptoms referable to the heart consist of angina pectoris or complaints due to congestive heart failure. Angina pectoris is due to severe coronary arteriosclerosis which often accompanies myxedema It often is not present until after the administration of thyroid and the elevation of the basal metabolic rate

On examination there are signs associated with advanced myxedema which are similar to those of congestive heart failure. Thus there are peripheral edemas, ascites, pleural effusion and hydropericardium which have not responded to digitalis or diuretics The skin is cool and dry. The blood pressure shows no constant or significant change.

The heart is definitely enlarged in advanced myxedema. In some instances the enlargement is apparent only, for there is a pericardial effusion rather than dilatation or hypertrophy of the heart itself. In either case it may be difficult or impossible to feel a precordial pulsation or to localize the apical impulse. The heart sounds are enfeebled

The electrocardiographic changes consist of low voltage of all the complexes, but most frequently of T and P, and flattening or inversion of the T waves An increased voltage of the ventricular complexes follows thyroid therapy.

Myxedema may be recognized at times from the cold, dry, thickened skin, scanty hair and eyebrows, puffy eyelids, and mental and physical sluggishness, constipation and intolerance to cold The basal metabolic rate is usually between —25 and —35 per cent There are cardiac enlargement, low voltage and flattening and inversion of the T waves in the electrocardiogram in patients who have myxedema. Diagnostic confirmation is obtained by restoration of a normal cardiac function on administration of adequate amounts of thyroid.

Radioactive iodine may be employed when the history and the findings on examination are inconclusive for a diagnosis of heart disease resulting from myxedema

Cardiac and Circulatory Decompensation (Congestive Heart Failure). The term congestive heart failure designates a state or a condition which results when the myocardium is unable to perform, or is prevented from performing, its functional tasks The term is not desirable when used to define a diagnosis, but it may be the only diagnostic descriptive term which can be assigned in a particular instance of heart failure and under these circumstances such a diagnosis is acceptable.

The precipitating causes for the onset of congestive heart failure can be determined in about one half of those who have heart failure These causes are infection, inadequate coronary blood flow, changes in rate and rhythm, pregnancy and childbirth, anemia, pulmonary embolism, transfusion of blood and of sodium-containing [illegible] a person who has

[illegible] :ase such as diphtheria, or in cases of multiple coronary occlusions with extensive myocardial fibrosis and infarction, probably is caused by destruction of a sufficient amount of muscle tissue to cause impairment of its contractility to such extent that the heart is unable to maintain the circulation, for, as a rule, the lesions of rheumatic, hypertensive, arteriosclerotic, syphilitic and other forms of heart disease remain essentially the same during heart failure The immediate lack of correlation between the lesions present in the heart and heart failure may be inapparent. However, impending heart failure is manifested by certain reliable criteria which can be recognized Edema is a most important manifestation of myocardial failure and this is a product of deranged sodium excretion Therefore the generally accepted conception of heart failure recognizes the importance of deranged sodium excretion and edema in heart failure but also recognizes the importance of a weakened cardiac muscle.

Clinical manifestations which are considered evidence of myocardial insufficiency have their origin in the failure of heart muscle in ventricular contraction

The cardiac *symptoms* often start with palpitation, fatigue and rapid heart beat Breathlessness and peripheral edema develop early. Progressive dyspnea, orthopnea, attacks of cardiac asthma or pulmonary edema appear. Increasing subcutaneous edema, serous effusions, engorgement of the cervical veins and enlargement of the liver result from failure of the right side of the heart which is added to the existing failure of the left side of the heart. Shock may result from acute cardiac failure or from acute peripheral vasodilatation.

Vitamin B_1 deficiency or beriberi heart disease may be first manifested soon after surgical operation in chronic alcoholics.

Examination reveals an enlarged heart with an enfeebled first heart sound accompanied by systolic murmurs, a gallop rhythm and a fast pulse rate. The blood pressure is normal The superficial veins are engorged. There are the neurologic evidences of beriberi The electrocardiogram may disclose depressed diphasic or inverted T waves. Low voltage of the QRS complexes and a prolongation of the QT interval are present. Roentgenologic examination often reveals cardiac enlargement

The diagnosis of beriberi heart is considered in all cases of unexplained cardiac enlargement or unexplained cardiac failure, particularly in patients less than 45 years of age, and in postoperative heart failure in chronic alcoholics The diagnosis is based on the presence of the cardiovascular abnormalities in association with peripheral neuritis There may also be concomitant signs of pellagra and occasionally of scurvy

The Myocardium in Endocrine Diseases. *Hyperthyroidism.* Kepler and Barnes found organic heart disease in 18 of 27 instances of fatal hyperthyroidism in which there had been evidence of congestive heart failure.

Hyperthyroidism is common between the ages of 20 and 40 years. In contrast, thyroid heart disease before the age of 40 years is not common. In 108 patients who had thyroid heart disease recorded by Barker and others the average age was 51 5 years, an age which seems to antedate the average age for the appearance of hypertensive arteriosclerosis

Women have hyperthyroidism more frequently than men, in a ratio of 5 1 However, men who have hyperthyroidism have heart disease much more frequently.

Thyroid heart disease is often manifested by auricular fibrillation, cardiac enlargement and heart failure Whether or not this so-called thyroid heart disease is the manifestation of a coexistent independent heart disease is often very difficult to determine, for the basal metabolic rate may be equivocal, and too it may be elevated in hypertension Studies of radioactive iodine and protein-bound iodine seem to make the differentiation more precise. The normal heart is capable of adjusting itself for a long time to the requirements imposed by excessive thyroid secretion and increased metabolism However, the added work of hypertension and the diminished cardiac efficiency due to myocardial anoxia may render the heart unable to maintain its normal size and remain compensated

The diagnosis requires first the recognition of the presence of hyperthyroidism This can usually be most quickly done by the determination and proper interpretation of the basal metabolic rate Heart disease associated with hyperthyroidism or adenomatous goiter can often be diagnosed if attempts are made to account for the presence of a paroxysmal or persistent auricular fibrillation of undetermined heart failure without apparent cause, heart failure which does not respond well or at all to digitalis; heart disease with unexplained tachycardia, and the presence of congestive heart failure without arteriosclerosis, rheumatic valvular heart disease, fever, anemia or vitamin B_1 deficiency. In borderline instances of hyperthyroidism, radioactive iodine may be diagnostic if it is properly employed and the results are correctly interpreted (see Diseases of the Thyroid, Chapter 14).

Myxedema. Myxedema is characterized by a reduction in basal metabolism. It

the age of 40 years it usually is due to rheumatic fever. Left ventricular failure after the age of 40 years is generally caused by hypertension, coronary artery disease, aortic valvular disease or rheumatic fever.

Left ventricular failure arises when dilatation and hypertrophy of the left side of the heart cannot maintain an adequate cardiac output. This inability results first in an increased volume and pressure of blood in the left side of the heart followed by a rise of pressure in the pulmonary veins and capillaries

The symptoms of left ventricular failure arise from the engorgement of the lungs. The resulting rigidity and loss of elasticity of the lungs from engorgement interfere with respiratory movements; and a reduction in vital capacity, impairment of diffusion of oxygen and slowing of the pulmonary circulation ensue.

The lungs in left ventricular failure are more solid than normal and dark red in color. In long-standing pulmonary congestion the lung is usually dry, indurated, and brown owing to deposition of hemosiderin (brown induration of the lungs). Pulmonary emboli and infarcts, hemorrhages, hypostatic congestion, bronchopneumonia and bronchitis are concomitants of this form of congestive heart failure.

SYMPTOMS. One of the first symptoms of left ventricular failure is prolongation of breathlessness after exertion which soon becomes dyspnea Dyspnea is respiratory distress associated with increased effort in breathing It is of a panting or puffing quality and not an inability to take a deep breath Cardiac dyspnea is characterized by rapid, shallow respirations, and is precipitated by exertions previously performed without discomfort At first it occurs only with moderately severe exertions.

The excessive work of the muscles of respiration and the use of muscles not ordinarily required in unconscious breathing to distend and deflate the rigid lungs may be causes for the subjective distress of dyspnea which is localized in the upper part of the abdomen, the thoracic wall and the neck.

Paroxysmal dyspnea, paroxysmal nocturnal dyspnea and cardiac asthma are the forms of respiratory distress which appear in attacks during the day and the night. All of these dyspneas are due to pulmonary congestion The term cardiac asthma is employed synonymously with paroxysmal dyspnea because the wheezing character of the respiration and the signs in the lungs resemble those in bronchial asthma. Paroxysmal dyspnea may or may not occur in those suffering from exertional dyspnea and from orthopnea Often a patient is comfortable during the day but becomes distressed by dyspnea at night, or all of the attacks may occur during the day

The attack of nocturnal dyspnea often commences an hour or two after the patient has fallen asleep Cough, bad dreams, recumbent position, and abdominal distention are causative factors in the production of nocturnal dyspnea In the attack the patient awakens with a sense of suffocation Relief from mild attacks is obtained by sitting up, or after coughing up and expectorating thick mucus, often blood-tinged

In severe attacks the distress is intense and prolonged The patient, as during an attack of asthma, sits upright in bed and tries to get more air. The breathing is regular, rapid and often noisy owing to bubbling or gurgling sounds caused by moisture in the lungs The attacks may follow each other in rapid succession if a hypodermic injection of morphine is not administered. The following day the patient may feel well, but more often is exhausted and breathless

During the attacks of cardiac asthma the severity of pulmonary congestion is increased. Rales appear in the lungs or, if rales already are present, they become more extensive The second pulmonic sound becomes more accentuated and may be more distinct than the second aortic sound

Cardiac orthopnea is a symptom of left-sided heart failure and is due, like the various forms of dyspnea, to pulmonary congestion Orthopnea is the form of dyspnea which occurs when the patient assumes a recumbent position There is an increase in pulmonary congestion in the recumbent position, for there is a shift of blood to the thorax from the lower extremities and splanchnic viscera In the re-

adequately to supply the tissues with blood. There is thus a gradual or sudden dropping off of the ability of the heart to continue to increase, absolutely or relatively, the ventricular output in response to the demands.

Apparently the circulation in the kidneys is most sensitive to changes in the general circulation, and renal blood flow is the first to be affected by relative or absolute decrease in cardiac output. The kidneys promptly effect a shift in blood volume flow and secondarily in salt and water metabolism. The urinary output may be reduced to a fifth of normal, and yet there is specifically only sodium retention.

The secondary constriction of the efferent arteries may insure a normal glomerular filtration of sodium but not a normal excretion of sodium since tubular reabsorption of sodium has become supernormal. The kidneys and tissues seem to hold tenaciously to sodium in patients who have congestive failure. The retention of the sodium has been held responsible for the increased blood volume and the rise in venous pressure.

In human beings the larger the heart, the less is its mechanical efficiency. The physicochemical disadvantage of the hypertrophied heart with respect to oxygenation becomes intensified in the presence of tachycardia. For any given cardiac output, the oxygen requirement increases with an increase in cardiac rate. The increase in cardiac rate shortens the diastolic period, during which almost all of the oxygen diffusion occurs.

The theories of heart failure have been based on data obtained from catheterization of the right atrium, right ventricle and pulmonary artery.

The Theory of Backward Pressure Heart Failure. The classic example of congestive or backward pressure heart failure, according to Harrison, and Heyer and Harrison, *develops as the gradient of blood flow between the pulmonary and aortic systems* drops off and as increased blood mass accumulates in the venous channels back of the heart. The rate of accumulation of this blood mass determines the extent and character of the clinical symptoms. In the suddenly developing acute insufficiency extreme dyspnea and orthopnea develop and acute pulmonary edema promptly ensues. In chronic insidious congestive heart failure, besides pulmonary congestion the right ventricle also fails, with ensuing engorgement of the liver and ascites accumulating very late and producing edema in the dependent parts.

Chronic backward failure is the traditional congestive failure, with low cardiac output and low pulse pressure. *It is found in myocarditis of coronary atherosclerotic origin*, myocardial infarction, rheumatic myocarditis, diastolic hypertension, hypothyroidism, heart tamponade and pericardial constriction.

This backward or congestive failure often appears early in rheumatic carditis or coronary insufficiency *while there is still considerable myocardial reserve.*

The Theory of Circulatory Forward Propulsion Failure. In forward, or circulatory, failure there is normal or supernormal yet inadequate performance of the left ventricle. Acute forward circulatory failure occurs in cardiac standstill, extreme bradycardia or tachycardia, shock and hemorrhage. Chronic circulatory forward failure of the type *with high systolic cardiac output and high pulse pressure,* yet insufficient minute volume of blood flow, occurs in rheumatic or syphilitic aortic regurgitations, systolic hypertension, hyperthyroidism, arteriovenous shunt, congenital lesions, anemia and beriberi.

In these conditions the cardiac output in failure has been shown to be normal or [illegible] increased but still inadequate. The minute volume circulation *is not* greatly [illegible] may

C[illegible]

Congestive heart failure may originate from disease of either the [illegible] side of the heart

Failure of the left ventricle of the heart is the commonest and therefore the most important form of congestive heart failure. It always is the result of a failure of the myocardium of the left ventricle to perform its assigned task. When it occurs before

sounds. Gallop rhythm is present only when there is tachycardia. Auricular fibrillation is frequent in all forms of left-sided heart failure but commonest in rheumatic carditis.

Alternation of the pulse may be a sign of left ventricular failure. It is recognized by inflating the cuff to the systolic pressure. As the cuff is very slowly deflated, only alternate beats are heard for a distance of 2 to 10 mm or more of mercury below the systolic level. Rarely pulsus alternans is recognizable by palpation of the radial pulse; unlike premature beats of pulsus bigeminus, the weak beat is very slightly closer to the succeeding beat than to the preceding one. The heart sounds do not usually appear to be modified, but graphic records have demonstrated such alternation in intensity of the sounds Alternation of the QRS or T wave or of any other wave in the electrocardiogram may be associated with pulsus alternans.

The signs of basal rales and emphysema usually are those of a functional emphysema. Between attacks of cardiac asthma or pulmonary edema there may be no rales at the bases of the lungs posteriorly. When rales are present they often are unilateral and predominantly on the right side. During or immediately after an attack of cardiac asthma there may be many sonorous or sibilant rales resembling the rhonchi of bronchial asthma With pulmonary edema, fine and coarse moist rales become more extensive and the entire thorax may be filled with bubbling or gurgling sounds. In addition there may be signs of a complicating bronchitis, bronchiectasis, bronchopneumonia or pulmonary infarction

Hydrothorax in the course of congestive heart failure appears on the right side.

Edema is an important finding in left-sided heart failure Sodium-water retention is a primary prerequisite for the development of edema, but edema is not necessarily a direct consequence of salt-water retention Hypervolemia, increased venous return to an incompetent cardiac chamber, and increased venous pressure are a sequence of events which determine the appearance and localization of edema after renal retention of sodium and water occurs

The reduction in blood proteins in most cases of heart failure is relatively too small to cause edema. Occasionally the blood protein is low enough as in cases of constrictive pericarditis to cause edema Edema occurs when the concentration of serum protein is less than 5 gm per 100 ml (albumin less than 2 5 gm per 100 ml)

Circulatory measurements are altered in left-sided heart failure The circulation time is prolonged The arm-to-tongue time exceeds the upper limit of normal, 16 seconds, and may be 40 seconds or more. The vital capacity is diminished The venous pressure is normal in the absence of concomitant right-sided heart failure.

The basal metabolic rate may be slightly or greatly elevated

Diagnosis. The diagnosis of left-sided heart failure is made on the basis of the symptoms and signs of pulmonary congestion in a person who has the types of cardiac diseases which usually lead to left-sided heart failure.

The diagnosis of left-sided heart failure involves often the distinction of left heart failure from bronchopulmonary disease, as suggested by such symptoms as cough, dyspnea, hemoptysis and asthma Roentgenograms of the thorax and physical and electrocardiographic examination to determine the presence of underlying cardiac disease are helpful The history may provide the diagnostic data that are not otherwise available A prolonged circulation time distinguishes cardiac from bronchial asthma

Congestive Heart Failure Associated With Failure of the Right Ventricle. When the entire myocardium is weakened sufficiently to cause symptoms of heart failure, the weak right ventricle yields first

The primary diseases of the lungs which cause right-sided heart failure are: Disease of pulmonary vessels or of the pulmonic valve causes strain and consequent

cumbent position, the cardiac output and the venous return are augmented The diaphragm is elevated and consequently this interferes with thoracic breathing because of shortening the thoracic compartment available for expansion This mechanical factor is more important in the presence of ascites and enlarged liver and abdominal tympanites. An enlarged liver and ascites elevate the diaphragm as well as interfering with diaphragmatic movements. It is strangely true that in some patients an orthopnea may occur in one recumbent position, for instance, on the left side, but not in another (trepopnea).

Clinical manifestations of pulmonary edema may be observed in patients suffering from cardiac asthma, but it may appear for the first time in a patient while an attack of coronary occlusion is in progress, during a hypertensive crisis, or after transfusions or intravenous infusions

Acute pulmonary edema is manifested by intense dyspnea, orthopnea, cough, extreme anxiety, and noisy gurgling or bubbling sounds Often there is intense precordial oppression or pain There may be a transition of an attack of cardiac asthma into one of pulmonary edema. In severe attacks the patient drowns from the profuse secretions which cannot empty rapidly enough from the nose and mouth The sputum is frothy and pink-stained because of the presence of blood

The patient is cyanotic, the skin is covered by a cold sweat The pulse is full but if relief is not obtained it becomes rapid and weak

The attack of pulmonary edema usually subsides spontaneously after a few minutes or hours, after coughing up of some blood-stained, frothy sputum. The attack may be rapidly controlled by an injection of morphine, the application of tourniquets to the extremities, or a generous venesection While any given attack usually subsides spontaneously or with treatment, acute pulmonary edema may end fatally. In those who recover, temporary exhaustion follows the attack.

Pulmonary edema and cardiac asthma are less frequent in left ventricular failure due to mitral stenosis than in left ventricular failure due to hypertension, despite the presence of long-standing congestion in the former.

Cough commences with the attack of dyspnea and with pulmonary edema in patients who have left-sided heart failure It may be present in the intervals between attacks, it is very likely to be worse at night The cough of heart failure is induced only by exertion or recumbency In elderly patients a cough and bronchitis, without or with mild fever, may have its origin in congestive heart failure.

In mitral stenosis cough is often an important symptom. A cough may have its origin from other causes such as bronchitis or to a large left atrium or pulmonary artery compressing a bronchus, or to a congenital double aortic arch, or from mediastinal tumor

Hemoptysis in mitral stenosis is common, in hypertensive heart failure uncommon It usually is due to congestion of the lungs but it may be associated with pulmonary embolism and infarction

Examination. Enlargement of the heart may be revealed by inspection and palpation of the apical impulse, by percussion and by roentgenologic examination.

The arterial blood pressure may be unchanged, may fall or may become elevated, depending in large measure on the underlying disease and the factors precipitating heart failure.

In left-sided heart failure, accentuation of the second pulmonic sound is due to the high tension in the pulmonary artery The second pulmonic sound may become louder than the second aortic sound even when there is present systemic hypertension.

An apical systolic murmur is frequently present owing to a relative mitral insufficiency. Tachycardia is frequent Ticktack sounds (embryocardia) may result from shortening of diastole by tachycardia with consequent even spacing of the two

EXAMINATION. On examination of one who has right ventricular heart failure, subcutaneous edema and venous congestion are the most definite findings In ambulatory patients the edema may be present in the evening and absent after a night's rest in bed. In a patient who has been in bed for some days or longer, the edema is most prominent over the sacral region. Sometimes there is generalized, massive edema (anasarca) affecting all parts of the body including the genitalia, thoracic wall, arms and face. A considerable amount of fluid may accumulate in the subcutaneous tissues before edema becomes apparent.

Prominence of the superficial veins is an early sign of right-sided heart failure and may be noticeable before there is detectable subcutaneous edema, hepatic enlargement or other signs of heart failure

Cyanosis is almost constantly present in those who have right ventricular heart failure. It may result from a secondary pulmonary disease or a congenital cardiac lesion causing admixture of arterial and venous blood. In most cases of combined right ventricular and left ventricular heart failure, cyanosis is a prominent manifestation.

Cardiac enlargement is present and it is more pronounced than in left heart failure. In those who have right-sided heart failure secondary to intrinsic pulmonary disease the enlargement of the heart is often difficult to demonstrate. The cardiac size is demonstrated with ease in those who have tricuspid insufficiency and stenosis and those who have a constrictive pericarditis with failure.

Hydrothorax is a common finding of right ventricular heart failure. These pleural effusions in right-sided heart failure occur oftenest in the right pleural cavity or are most extensive on that side when there are bilateral effusions

Hepatic enlargement is often present before there is edema and may remain after the edema has disappeared In the presence of severe heart failure, if there is significant tricuspid valvular insufficiency or auricular fibrillation, the liver pulsates synchronously with the right ventricular pulsations Abdominal pressure over the engorged liver causes or increases visible engorgement of the cervical veins and a rise in venous pressure

The large liver may be tender and painful. The urobilinogen in the urine is increased Hyperbilirubinemia is frequently present, but it is not usually sufficient to produce jaundice The van den Bergh reaction is often delayed or indirect. An impairment of hepatic function may be indicated by excessive retention of injected sulfobromophthalein sodium. Ascites is commonly present.

The urine is concentrated and has a high specific gravity. When cardiac edema disappears the specific gravity is low. The specific gravity of the urine remains low if cardiac failure has complicated a renal insufficiency, or after frequent administration of mercurial diuretics, or prolonged and extreme restriction of sodium intake.

The concentration of sodium in the *plasma* is diminished despite the reduction in urinary sodium

The concentration of chloride in the plasma may be normal when the plasma sodium is depressed if there is a low carbon dioxide-combining power and a tendency to acidosis In the presence of renal insufficiency both plasma sodium and chloride are diminished in concentration, with evidence of acidosis due to retention of fixed acids

Slight albuminuria is common in congestive heart failure Hyaline, granular and epithelial casts are present

Moderate *azotemia*, as indicated by urea nitrogen between 20 and 40 mg. per 100 ml of blood, is the rule Hypoproteinemia is rare but may occur after prolonged heart failure from an ensuing malnutrition, impaired hepatic function, and a long-continued loss of albumin in the urine.

The circulation time is prolonged. The blood volume is augmented The venous

failure of the right ventricle (cor pulmonale). Isolated tricuspid stenosis may cause failure of the right atrium and an ensuing failure of the right ventricle Obstruction to the inflow of blood into the right atrium such as constrictive pericarditis and prolonged ectopic tachycardias may lead to right-sided heart failure. Renal retention of sodium and water augments the circulating blood volume and venous return to the right atrium and ventricle. The incompetent right heart is unable to accept and expel this venous return, and blood is dammed up in the systemic veins and capillaries (Friedberg)

PATHOLOGY The lungs are congested. The liver is dark red or brownish, enlarged and firm because of chronic passive congestion In cases of long standing the liver may have undergone atrophy so that it may be smaller than normal. The term nutmeg liver refers to the appearance produced by the alternation of dark red and light brown areas When the process of connective tissue replacement and fibrous retraction is extensive, the changes in the liver are described as cardiac cirrhosis Ascites is common.

There is passive congestion of the spleen, which is enlarged, dark red and firm The pancreas may also be affected by passive congestion. The kidneys are dark red and are firmer than usual. Heart failure does not cause contraction of the kidneys.

The brain is sometimes infarcted and softened

SYMPTOMS The symptoms of right-sided and left-sided heart failure are usually combined, and often they appear simultaneously or so nearly so that clinically the symptoms are the same in both cases except for the general symptoms of the condition which may be the cause of failure of the right side of the heart

The symptoms of right-sided heart failure are largely due to engorgement and elevation in pressure of the systemic veins and capillaries and the associated sodium-water retention

Fever is often present and is due to an associated pulmonary infarction or bronchopneumonia, rheumatic activity, bacterial endocarditis or some other infection. Pain attends the fever and may be helpful in determining its cause.

Weakness is a definite symptom in advanced failure, and is sometimes associated with extreme loss of weight and anemia Excessive treatment administered by mouth and by vein may add to the weakness already present.

Owing to venous engorgement and medications, anorexia and abdominal distention or a sense of fullness after meals is frequent Nausea and vomiting attend the gastric congestion and may be enhanced by excessive use of digitalis, morphine and the enthusiastic use of chemotherapy and antibiotics The combination of meteorism with hepatic enlargement and sometimes also ascites and constipation may cause fecal impaction in the colon or rectum In an occasional instance of right heart failure with fecal impaction a period of observation may be required to be certain colonic obstruction is not present

Nocturia and polyuria are frequently present but these symptoms are not due to heart failure Often they are due to irritation of the bladder or urethra by concentrated urine. Nocturia in men may be due to an enlarged prostate gland In either men or women nocturia may be occasioned by the elimination of occult edematous fluid Oliguria is a characteristic feature of right-sided heart failure. On improvement the volume of urine increases. In some instances of spontaneous or therapeutic diuresis a urinary volume of several liters may be voided in a day.

Headache, insomnia and mental depression may arise if the patient is aware of the serious danger to life that heart failure imparts. Delirium, hallucinations and delusions of a paranoid type and extreme weakness may follow excessive diuresis and loss of sodium chloride Morphine, barbiturates and digitalis may be contributory causes of mental symptoms, for heart failure alone usually does not cause mental symptoms. The loss of potassium may contribute to the production of these symptoms.

Aphasia, paralyses, convulsions and coma may be due to a complicating cerebral infarction.

The painless character of pericarditis in uremia and other terminal diseases is explained by the absence of pleuropericarditis.

Acute Pericarditis. An acute pericarditis comprises acute fibrinous pericarditis and purulent pericarditis

Acute fibrinous pericarditis is usually a part of the pericarditis of acute rheumatic fever. It is characterized by a sterile pericardial effusion The etiology is unknown. The disease occurs in young adults and shortly after a mild infection of the upper part of the respiratory tract. The initial pain, physical findings, and electrocardiographic abnormalities may simulate acute myocardial infarction. The disease subsides spontaneously within a few weeks but occasionally produces an adhesive pericarditis.

The symptoms vary in intensity and consist of pain and, if effusion is present, dyspnea There may be some fever.

On examination a pericardial friction rub is present. A pericardial friction rub may be associated with a dry fibrinous pericarditis or it may be heard in the presence of a pericardial effusion. A pericardial rub is a sign of an acute fibrinous pericarditis, with or without an effusion.

On auscultation a pericardial friction rub is heard as a superficial, scraping, scratchy or grating sound or occasionally one with a coarse squeaking quality, a sound often described as being similar to that of squeaking leather. There are usually to-and-fro sounds, due to vibrations set up during ventricular and auricular systole.

The pericardial rub is heard just to the left of the lower one third of the sternum It is well localized to a small area. The point at which it is best heard may shift with a change in the patient's position The loudness of the rub is intensified if the patient leans forward and moderate pressure is made on the thoracic wall with the stethoscope The pericardial rubs may be audible for only a few hours at a time and intermittently. Occasionally they persist for weeks or even months.

Purulent pericarditis is the commonest form of pericarditis. The causative organisms are usually the staphylococci, the pneumococci and the hemolytic streptococci A variety of other microorganisms are occasionally responsible, including the meningococcus and *Pasteurella tularensis*.

A purulent pericarditis arises by direct extension of an intrathoracic or intra-abdominal infection, by hematogenous bacterial dissemination, or by traumatic introduction of bacteria through the thoracic wall Staphylococcal or streptococcal septicemia and pneumococcal or streptococcal empyema, especially of the left pleural cavity, are commonly associated Bacterial pericarditis, like pleuritis, may be fibrinous at its onset and then serofibrinous or serohemorrhagic before it becomes purulent

Unexplained dyspnea, cyanosis, venous engorgement about the head and neck, falling blood pressure and weak rapid pulse in a patient who is ill from thoracic or abdominal infection or from septicemia and osteomyelitis, may be manifestations of acute pericarditis The prevailing symptoms referable to a pericarditis are dyspnea and pain.

Compression of the trachea, bronchi and lungs caused by the distended pericardium produces dyspnea The respiratory embarrassment may become critical.

Pain is present in only half of the seriously ill patients It is precordial in situation and often extends to the left shoulder and arm, the neck, the epigastrium and the left scapular regions. The pain is intensified by deep inspiration, by movement of the thoracic wall and by cough

On examination the patient is restless, cyanotic or pale, sits up and leans forward and does not want to be annoyed by examinations.

The cardiac impulse is weak or absent The heart sounds are enfeebled. In some instances the apical impulses and heart beats remain visible, palpable and audible in the presence of massive effusions.

pressure is elevated in contrast with the normal venous pressure in failure of the left ventricle. The arterial blood pressure undergoes no characteristic change

DIAGNOSIS. The diagnosis of right-sided heart failure in those known to have left-sided heart failure is made easily by the appearance of the combination of congested cervical and peripheral veins, subcutaneous edema of the dependent parts, and hepatic enlargement. Right heart failure is easily diagnosed in those who have primary disease of the lungs. A severe reaction following the intravenous infusion of isotonic saline solution and characterized by evidences of an increased venous pressure may be the first indication of right-sided heart failure in a patient who has left-sided heart failure or a weak myocardium.

The *course* of congestive heart failure is often determined or modified by the underlying cardiac disease.

In most reports of studies on *prognosis* in heart failure it is stated that the duration of life in cardiac disease complicated by right heart failure is usually 1 to 2 years, rarely is it 5 years

In general, the prognosis is relatively favorable if the symptoms of congestive failure subside rapidly and completely with appropriate treatment.

The prognosis in any particular instance of congestive heart failure should be guarded even when it appears relatively favorable, because of the danger of serious complications or sudden death.

THE PERICARDIUM

The pericardium is composed of fibrous tissue lined with serous membrane.

The pericardium is somewhat conical in shape Its base rests on the central tendon of the diaphragm, and its apex envelops the great vessels, as they emerge from the base of the heart, for a distance of 1⅔ to 2 inches (about 4 to 5 cm) The attachment to the diaphragm is firmest at the opening of the inferior vena cava As the fibrous layer of the pericardium proceeds upward, it becomes lost in the fibrous tissue (sheath) covering the great vessels. This is continuous above with the deep cervical fascia, especially with its pretracheal layer.

On each side the pleura and the pericardium are in contact, with the phrenic nerve and its accompanying vessels between them. Posteriorly the pericardium lies on the bronchi, the esophagus, and the thoracic aorta

Owing to its fibrous nature, the pericardium will not expand rapidly. When a pericardial effusion attains a large size it creates an increased mediastinal pressure and causes circulatory symptoms by obstruction of the circulation at the base of the heart; respiratory symptoms by pressure on the bronchi; and digestive symptoms from pressure on the esophagus and displacement of the stomach and liver downward. There are alterations in or loss of the voice from pressure on the recurrent left laryngeal nerve (see Mediastinal Tumors, Chapter 9).

Pericardiac Pain. Paracentesis of the pericardium at the level of the fifth and sixth interspaces near the mammary line elicits pain, sharp and restricted to a point over the trapezius ridge. Penetration of the pericardium at higher levels does not produce pain. This pain is similar to that caused by irritation of the central portion of the diaphragmatic pleura It is therefore evidence that the phrenic nerve endings are reflected over the lower portion of the fibrous pericardium

According to Capps scratching or pressure on the heart itself produces no pain The inner surface or serous layer of the pericardium gives no pain response to irritation

When pain is present with an acute fibrinous pericarditis, it is due to involvement of the pleuropericardial surfaces, if the pleura anterior or posterior to the sac is affected, the pain is sternal or posterior, if the diaphragmatic pleura is inflamed, the pain is referred to the neck or to the abdomen. This pain is nearly always excited by cough, deep breath or change of posture.

In heavy infection the cardiac symptoms and findings resemble those of beriberi. There are edema, dilatation of the heart and congestive heart failure The cerebral symptoms are those of cerebral hemorrhage or thrombosis.

The diagnosis is established by finding the characteristic ova in the feces in association with heart failure otherwise unexplained. The ova of *Clonorchis sinensis*, various species of *Opisthorchis, Heterophyes heterophyes,* and other heterophyid flukes resemble those of *Metagonimus yokogawai*.

TUMORS OF THE HEART

Tumors of the heart and pericardium are relatively unimportant as a cause of clinical heart disease. These tumors occur in either benign or malignant forms The benign tumors are myxoma, rhabdomyoma, fibroma, lipoma, angioma, papilloma, teratoma, leiomyoma, and xanthoma The malignant tumors occur as sarcoma, mesothelioma or mesothelial sarcoma of the pericardium, rhabdomyosarcoma, and epicardial epitheliomas.

Secondary malignant tumors which are occasionally present are carcinoma and sarcoma by direct invasion or sarcoma by metastasis

Hodgkin's disease, lymphosarcoma, leukemia and Kaposi's sarcoma may affect the heart

SYMPTOMS Most cardiac tumors do not produce clinical symptoms and are discovered only at postmortem examination.

Symptoms of congestive heart failure are generally regarded as the commonest manifestations of cardiac neoplasms. The heart failure due to cardiac tumors is characterized by its sudden and unexplained development, intractability, rapidly progressive course and its failure to respond to therapy

The Superior Caval Syndrome. The superior caval syndrome results from lymphomatous, metastatic or primary malignant neoplasms of the pericardium The onset is often with cough, malaise and fever Later the full clinical syndrome develops which consists of increasing dyspnea, engorgement of the cervical veins, enlargement of the liver, and small rapid pulse

DIAGNOSIS Occasionally a correct antemortem diagnosis of secondary (malignant) tumors of the heart is made Primary tumors also have been recognized during life.

The diagnosis depends on alert awareness that cardiac neoplasm may be responsible for cardiac manifestations, especially when the clinical course is atypical. In the presence of a malignant neoplasm elsewhere in the body, especially in the neighboring thoracic organs, the onset of rapid heart failure is significant.

CONGENITAL HEART DISEASE

Heart disease prior to the age of 5 years is usually of congenital origin. In older children who have heart ailments, the disorder in about 1 in every 10 is congenital. Among adults congenital heart disease accounts for an insignificant part of the total who are disabled from heart disease

The incidence of congenital heart disease is equally divided between the sexes

ETIOLOGY In congenital heart disease it is not known whether the defect is an intrinsic factor in the germ plasm or an extrinsic factor in the environment of the embryo It is rare to have a positive genealogic history of manifest congenital heart disease unassociated with another anomaly of the heart or the body

The occasional occurrence of rubella (German measles) in the first trimester of pregnancy is [illegible]
anomalies in [illegible]
cause in occa [illegible]

PATHOLOGY In many instances of congenital heart disease there is maldevelopment of different structures in the heart which are in close anatomic association. *In some* instances when there are abnormal changes in pressure in the chambers of the heart or

are a small and usually paradoxical pulse, low systolic blood pressure and especially a low *pulse pressure, and little* or no evidence of pulmonary congestion.

When the diagnosis is made, pericardiectomy is usually advisable.

Cardiac tamponade is manifested by a rising venous pressure, a falling arterial pressure, a small heart, tachycardia, a fall in blood pressure and clinical features of shock. This is a common form of heart failure in constrictive pericarditis

Systemic venous congestion is manifested by engorgement of the cervical veins, increased venous pressure, and enlargement of the liver. Cyanosis of the lips, face and neck and occasional facial edema is present

Paradoxical pulse, a distinct diminution in pulse amplitude during inspiration, may be associated with cardiac tamponade. It is best demonstrated by the fall in blood pressure of 10 to 20 or more, expressed in millimeters of mercury, at the end of inspiration A pulsus paradoxus is observed in any abnormal increase in pulmonary vascular capacity during inspiration, for instance, in laryngeal and tracheal obstruction.

Electrocardiographic abnormalities which seem to be distinctive are observed in more than one half of those who have pericarditis. There are changes in the ST segments and T waves and low voltage of all complexes. Similarities to the changes in myocardial infarction of the electrocardiograms may be confusing without the clinical history and physical and roentgenologic examinations

Paracentesis of the Pericardium. In tapping the pericardium by means of a trocar or aspirating needle care is exercised not to injure the pleura and the internal mammary arteries

The safest point is probably close to the left edge of the sternum in the sixth interspace. This interspace may not extend to the sternum, but even if the cartilages are in contact, a needle could probably be introduced at this point

The increased area in cases of distention from pericardial effusions has led to tapping in the fourth interspace, either at the left sternal margin or 1 inch (2 5 cm) from it, or at the fifth interspace 1½ inches (about 4 cm.) from the sternal margin, or by thrusting the needle upward and backward close to the costal margin in the left costoxiphoid angle

The Nature of Pericardial Fluids. *Hemopericardium* is commonly present in acute myocardial infarction due to coronary artery occlusion or follows rupture of the cardiac wall It may also be due to scurvy, leukemia or other hemorrhagic diseases The condition is usually manifested as a cardiac tamponade.

Hydropericardium is usually part of a generalized anasarca of congestive heart failure, glomerulonephritis and myxedema It may be part of a nutritional deficiency with hypoproteinemia. Hydropericardium may result from local causes which interfere with the venous return from the pericardial circulation, such as mediastinal tumors

Pneumopericardium results from traumatic perforation of the pericardium or perforation of a neighboring air-containing organ into the pericardium If there is a large quantity of air, there may be tympany on percussion of the precordium and metallic or clinking heart sounds on auscultation. If both fluid and air are present, loud, gurgling, splashing metallic sounds may be audible (bruit de moulin) There may also be a pericardial rub

Roentgenologic examination readily reveals the presence of air There may be a horizontal fluid level which moves with cardiac pulsations

PARASITIC DISEASES OF THE HEART

The heart and the heart muscle are susceptible to invasion by developmental forms of *Trichinella spiralis, Tinea solium, Echinococcus granulosus* and *Metagonimus yokogawai* and other less well known parasitic worms

The pathologic changes and symptoms are slight and the results of examination are essentially negative unless there is a systemic invasion by the ova, and then the symptoms are comparable to those present in the larval infection by the pork tapeworm.

In heavy infection the cardiac symptoms and findings resemble those of beriberi. There are edema, dilatation of the heart and congestive heart failure. The cerebral symptoms are those of cerebral hemorrhage or thrombosis.

The diagnosis is established by finding the characteristic ova in the feces in association with heart failure otherwise unexplained. The ova of *Clonorchis sinensis*, various species of *Opisthorchis*, *Heterophyes heterophyes*, and other heterophyid flukes resemble those of *Metagonimus yokogawai*

TUMORS OF THE HEART

Tumors of the heart and pericardium are relatively unimportant as a cause of clinical heart disease. These tumors occur in either benign or malignant forms. The benign tumors are myxoma, rhabdomyoma, fibroma, lipoma, angioma, papilloma, teratoma, leiomyoma, and xanthoma. The malignant tumors occur as sarcoma, mesothelioma or mesothelial sarcoma of the pericardium, rhabdomyosarcoma, and epicardial epitheliomas.

Secondary malignant tumors which are occasionally present are carcinoma and sarcoma by direct invasion or sarcoma by metastasis.

Hodgkin's disease, lymphosarcoma, leukemia and Kaposi's sarcoma may affect the heart.

SYMPTOMS. Most cardiac tumors do not produce clinical symptoms and are discovered only at postmortem examination.

Symptoms of congestive heart failure are generally regarded as the commonest manifestations of cardiac neoplasms The heart failure due to cardiac tumors is characterized by its sudden and unexplained development, intractability, rapidly progressive course and its failure to respond to therapy.

The Superior Caval Syndrome. The superior caval syndrome results from lymphomatous, metastatic or primary malignant neoplasms of the pericardium. The onset is often with cough, malaise and fever. Later the full clinical syndrome develops which consists of increasing dyspnea, engorgement of the cervical veins, enlargement of the liver, and small rapid pulse.

DIAGNOSIS Occasionally a correct antemortem diagnosis of secondary (malignant) tumors of the heart is made. Primary tumors also have been recognized during life.

The diagnosis depends on alert awareness that cardiac neoplasm may be responsible for cardiac manifestations, especially when the clinical course is atypical In the presence of a malignant neoplasm elsewhere in the body, especially in the neighboring thoracic organs, the onset of rapid heart failure is significant

CONGENITAL HEART DISEASE

Heart disease prior to the age of 5 years is usually of congenital origin In older children who have heart ailments, the disorder in about 1 in every 10 is congenital. Among adults congenital heart disease accounts for an insignificant part of the total who are disabled from heart disease.

The incidence of congenital heart disease is equally divided between the sexes.

ETIOLOGY In congenital heart disease it is not known whether the defect is an intrinsic factor in the germ plasm or an extrinsic factor in the environment of the embryo It is rare to have a positive genealogic history of manifest congenital heart disease unassociated with another anomaly of the heart or the body

The occasional occurrence of rubella (German measles) in the first trimester of pregnancy is associated with a significant incidence of congenital cataracts and cardiac anomalies in the offspring. Fetal endomyocarditis and syphilitic myocarditis may be the cause in occasional cases (see Viral Diseases, Chapter 17)

PATHOLOGY In many instances of congenital heart disease there is maldevelopment of different structures in the heart which are in close anatomic association. In some instances when there are abnormal changes in pressure in the chambers of the heart or

great vessels, the fetal openings may not close. For instance, a patent foramen ovale or a patent ductus arteriosus may serve as a compensatory mechanism when there is atresia or stenosis of a valvular orifice

SYMPTOMS Congenital heart disease symptomatically has been classified by Abbott into three groups· cyanotic, acyanotic, and potentially cyanotic, the last being subdivided according to the intensity of the cyanosis if cyanosis develops

Cyanosis. Cyanosis is usually associated with severe multiple cardiac anomalies which lead to death before the patient reaches the age of active childhood

When cyanosis appears at birth or shortly thereafter the child is called a blue baby or is said to have morbus caeruleus. The term blue baby should be used cautiously because cyanosis at birth is often due to pulmonary atelectasis or intracranial hemorrhage. Cyanosis may be absent at birth and may make its appearance later when a compensating open ductus arteriosus becomes obliterated

The cyanosis appears in the lips, tips of fingers or toes, nose, ears and mucous membranes In an interruption of the aortic isthmus, cyanosis is limited to the lower extremities

A secondary polycythemia is often associated with an intense cyanosis Erythrocyte counts of between 6,000,000 and 7,000,000 per cubic millimeter with concentrations of hemoglobin correspondingly elevated (110 to 130 per cent) are observed in a patient who has moderate cyanosis and occasionally higher in extreme polycythemia. Cyanosis appears when there is an oxygen unsaturation of 6 5 volumes per cent in the capillary blood

On decrease of the cardiac reserve there is dyspnea on exertion. Dyspnea may come in paroxysms and may be associated with an intensification of cyanosis and the presence of polycythemia Dyspnea if due to pulmonary congestion is accompanied by cough.

Cerebral anoxia is manifested by faintness, dizziness and headache. Severe cerebral anoxia may cause syncope, convulsions, delirium, paralyses and coma

Peripheral vascular disturbances in the extremities include coldness, numbness and tingling or pain irrespective of the presence or absence of cyanosis and polycythemia.

The origin of clubbing of the fingers and perhaps the toes, whether in those who have congenital heart disease or other conditions, is difficult to correlate with the recorded findings concerning oxygen unsaturation, capillary stasis, an increased blood flow and maximal heat elimination from the fingers (see The Hand, Chapter 6)

Acyanosis. In the absence of cardiac failure some congenital cardiac patients *may never have cyanosis Those who do not have cyanosis* do not have a venous arterial anastomosis.

EXAMINATION On examination the presence of a cardiac murmur, enlargement of the heart, or dyspnea, with or without cyanosis and clubbing, without bronchopulmonary disease or brain injury, which commenced in infancy or early childhood is indicative of congenital heart disease

In early infancy the *cardiac murmurs* of congenital heart disease tend to be generalized but in time they will assume the site of predilection for their maximal intensity and thus reveal their identification A rough, loud murmur with maximal intensity in the second left interspace near the sternum may be due to a pulmonic stenosis, patent ductus arteriosus, or the tetralogy of Fallot The murmur of pulmonary stenosis is systolic and the second pulmonic sound is enfeebled. The murmur of a patent ductus arteriosus is a machinery-like murmur extending through *all* or a greater part of the cardiac cycle In aortic septal defect the machinery-like murmur is loudest over the lower part of the sternum or in the fourth left interspace

A loud systolic murmur, with maximal intensity in the third or fourth interspace to the left of the sternum, often transmitted to the left scapular region, is present in

interventricular septal defect (maladie de Roger). If there is an associated mitral stenosis, a later diastolic apical murmur may be audible. Systolic murmurs in the interscapular regions, in the axilla or along the sternum are present in instances of adult coarctation of the aorta when there is a well-developed collateral circulation.

A definite thrill in the second, third or fourth left interspace near the sternum in the absence of acute thoracic trauma is significant of congenital heart disease.

Roentgenologic examination of the thorax is invaluable in confirming suspected instances of dextrocardia, coarctation of the aorta, right-sided aortic arch and other abnormal cardiac silhouettes indicating lesions which might otherwise not be suspected.

Angiocardiograms and *arteriograms* may give objective demonstration of coarctation of the aorta, patent ductus arteriosus, aortic arch anomalies and aneurysm. In cases of coarctation not only is the diagnosis made but the site and type, which are of greatest value in preoperative planning, are delineated Retrograde visualization is decisive in borderline instances of patent ductus arteriosus. The simultaneous opacification of aorta and pulmonary artery or the actual demonstration of the ductus is objective evidence of patency. Aortic arch anomalies can be outlined. In aneurysms that are filled with clot, often there is enough evidence in the aortogram to make the diagnosis. Angiocardiography is not a method without some potential hazard

In *studies of circulation time* the presence of a venous-arterial communication may be demonstrated by the administration of drugs (ether and saccharin) as in the tests for determining the circulation time. Such tests are particularly useful in instances of the tetralogy of Fallot and terminally in cases of auricular or ventricular septal defects or patent ductus arteriosus when the usual left-to-right communication has been reversed. These tests are useful in trilocular or bilocular hearts or in those patients in whom there are extensive septal defects.

Intracardiac catheterization is a test to be employed only by skilled hands and even then it is not without danger

COMPLICATIONS The complications of congenital heart disease are congestive heart failure, bacterial endocarditis, cerebral abscess or hemorrhage, and paradoxical embolism Pulmonary tuberculosis often is a serious complication of congenital heart disease

The term paradoxical embolism refers to the passage of a thrombus from systemic veins to the arterial circulation, usually through a patent foramen ovale. A diagnosis of paradoxical embolism during life cannot be made

SOME CLINICAL TYPES OF CONGENITAL HEART DISEASE

Atrial Septal Defects. The clinical syndrome associated with atrial septal defects occurs most often when the septal defect is combined with mitral stenosis

Symptoms may be absent Often a normal span of life is enjoyed If symptoms are present owing to an atrial septal defect, they frequently arise from an associated paroxysmal tachycardia and transient auricular fibrillation Once symptoms become manifest, they often terminate in congestive heart failure

On *physical examination* there may be a left-sided deformity of the thorax. Palpation and percussion reveal enlargement of the heart, the apex being displaced downward and to the left while the right border is extended to the right of the sternum

A loud systolic murmur, sometimes accompanied by a thrill, is heard in the second or third interspace near the left border of the sternum or at the apex In about one third of these patients there is an apical diastolic murmur of mitral stenosis. The second pulmonic sound often is accentuated

Electrocardiographic examination may reveal a right axis deviation or auricular fibrillation or right bundle-branch block.

The results of *surgical treatment* by attempts to close septal defects are encouraging

Ventricular Septal Defects (Roger's Disease). Ventricular septal defects are

often associated with dextroposition of the aorta and pulmonic stenosis as well as other defects. There are usually no symptoms due to the lesion itself. Sometimes cyanosis is present at birth but disappears.

On examination there is a prolonged, loud and harsh systolic murmur with maximal intensity in the third or fourth left interspace near the sternum. Rarely the murmur is loudest at the left of the xiphoid process Often it is transmitted to the back where it is heard in the left interscapular or subscapular region. The murmur may obscure the second sound. In about one third of the cases the murmur is accompanied by a systolic thrill.

The Tetralogy of Fallot. The combination of a ventricular septal defect with pulmonary stenosis, dextroposition of the aorta and right ventricular hypertrophy is known as the tetralogy of Fallot.

The lesions in the tetralogy of Fallot are attributable to two essential factors of maldevelopment: (1) an adequate clockwise torsion or even a counterclockwise torsion of the truncus and bulbus arteriosus and of the septum which divides this vascular tube and (2) persistence of the (reptilian) right aorta which normally atrophies

SYMPTOMS Cyanosis is present at birth or it may have appeared after several months of age when the ductus arteriosus closes The cyanosis may become intensified during exercise, pulmonary infections and late in the course of the disease when heart failure develops Suffusion of the eyeballs is often associated with secondary polycythemia

Dyspnea on exertion is common Paroxysmal attacks of dyspnea may occur, generally after exercise and accompanied by an intensification of cyanosis. The dyspnea may be intensified when the patient is erect (orthostatic dyspnea) Characteristically the patient who has tetralogy of Fallot assumes the squatting or knee-chest posture when dyspneic or freshly tired.

EXAMINATION. Precordial bulging, systolic pulsation in the second and third interspaces, and epigastric pulsation may be present and if so they are due to the hypertrophy of the right ventricle Usually there are a systolic murmur and thrill to the left of the sternum in the second or third interspace, occasionally in the fourth. The second pulmonic sound is normal, weak or absent

Clubbed fingers are usually present when cyanosis is of long duration In some instances clubbed fingers may be present without cyanosis (see The Hand, Chapter 6).

Patent Ductus Arteriosus. Anatomic closure of the ductus is normally accomplished by the end of the third postnatal month in 4 of every 5 who have this anomaly

In uncomplicated patency of the ductus arteriosus the higher pressure in the aorta permits blood from that vessel to pass into the pulmonary artery during both systole and diastole There may be a reversal of the flow during crying, sucking, coughing, pulmonary infections and in the presence of heart failure

SYMPTOMS When symptoms appear, they are most often dyspnea on exertion and palpitation

EXAMINATION. Those who have patent ductus are pale, slender, undernourished and poorly developed. The left ventricle is enlarged There is a long and rumbling murmur which may extend through the heart cycle The murmur may be diffuse but usually is localized or loudest in the second left interspace near the sternum The murmur may not be continuous, it may be a long systolic murmur with maximal intensity in the second left interspace, near the sternum In other instances only a diastolic murmur may be heard to the left of the sternum The second pulmonic sound is accentuated and may be reduplicated. There often is a continuous thrill over the precordium.

When the ductus arteriosus is widely patent, there is a high pulse pressure, and signs remindful of aortic regurgitation are present.

When surgical treatment is contemplated, the cardiologist must recognize whether the patent ductus arteriosus is or is not associated with cardiac anomalies In some cardiac anomalies patency of the ductus is essential to the maintenance of life, and therefore it is well to recognize such cases before attempting surgical intervention Some of these anomalies are. infantile coarctation of the aorta, transposition of the great vessels and pulmonary atresia and stenosis.

Persistent Truncus Arteriosus Communis. As the result of defective development of the bulbar septum there may be a common arterial trunk instead of distinct aorta and pulmonary artery.

If the pulmonary arteries arise directly from the truncus arteriosus, cyanosis is absent or minimal More often the circulation through the lungs is by way of dilated bronchial arteries; in such cases cyanosis is usually intense.

A harsh systolic murmur and thrill and cardiac enlargement are present. Roentgenologic examination discloses characteristic findings which are recognizable by the roentgenologist.

DISEASES OF THE THORACIC ARTERIES

DISEASES OF THE PULMONARY ARTERIES

Pulmonary Arteriolar Sclerosis. The existence of primary pulmonary arteriolar sclerosis cannot be proved during life

In secondary pulmonary arteriolar sclerosis, such as is present in chronic pulmonary emphysema, the small pulmonary arteries and arterioles may be the site of arteriosclerosis. The pulmonary arteriosclerotic lesions are probably secondary to pulmonary hypertension and not the cause. As a rule, the right ventricular enlargement in emphysema is due to secondary changes in the pulmonary capillary system which are unlikely to cause significant obstruction.

The manifestations of pulmonary arteriolar sclerosis are those of chronic cor pulmonale

Ayerza's Disease or Syndrome. The terms Ayerza's disease and Ayerza's syndrome refer to a clinical syndrome associated with bronchopulmonary symptoms and characterized by intense cyanosis, polycythemia and congestive heart failure. Formerly this disease was thought to be a syphilitic process

Pulmonary Arteriovenous Aneurysm. There are often cutaneous, mucosal and visceral angiomas, frequent occurrence of telangiectasia or recurrent epistaxis in parents or siblings (hereditary hemorrhagic telangiectasia).

The essential manifestations of pulmonary arteriovenous aneurysm are cyanosis and clubbing of the digits, in the presence of a normal heart, together with roentgenographic findings of a vascular tumefaction in the lung. Bleeding from the nose is common Hemoptysis may be lethal There may be headache, vertigo, weakness, syncope, convulsions, paresis or paresthesia of the extremities, dysphagia and hoarseness

There is an increase in the erythrocyte count and in the hemoglobin content. The total blood volume in the polycythemic cases is increased, but the plasma volume shows little or no increase in contradistinction to the observation in peripheral arteriovenous fistula The peripheral arterial oxygen saturation is decreased.

THE AORTA

The *ascending aorta* begins behind the left half of the sternum on a level with the lower border of the third costal cartilage It proceeds upward, forward and toward the right until it reaches the level of the lower border of the right second costal cartilage, where the horizontal portion of the arch begins

Immediately above its commencement it has three enlargements, two anteriorly and one posteriorly, called the sinuses of the aorta (Valsalva), which correspond to the semilunar valves From the sides of the posterior enlargement the right and left coronary arteries arise

Distal to the valves in the upper right portion of the arch, the aorta is again dilated, forming the great sinus of the arch of the aorta

The right limit of the aorta is about even with the right edge of the sternum; sometimes it projects slightly beyond. Because of the proximity of the aorta to the second interspace, it is here that the stethoscope is placed to hear aortic murmurs. The aorta at this point is covered only by the thin border of the right lung and pleura and the slight remains of the thymus

The first portion of the aorta is not united with the pericardium, but simply loosely covered by it, so that this portion of the arch is weaker than the other portions, and rupture, with extravasation of blood into the pericardial sac, is not uncommon

The *horizontal* or *transverse* and *descending* portions of the *aorta* pass anteroposteriorly from the upper border of the second right costal cartilage in front to the left side of the body of the fourth thoracic vertebra or its intervertebral disk posteriorly. This part of the aorta is about 2 inches (5 cm.) long Its undersurface is level with the angle of the sternum (angle of Ludwig), opposite the second costal cartilage Its upper surface rises as high as the middle of the first piece of the sternum, which is opposite the middle of the first costal cartilage, about 1 inch (2.5 cm.) below the top of the sternum. It describes a double curve in its course, with one concavity downward corresponding to the root of the left lung and another to the right corresponding to the trachea.

The *ductus arteriosus* at birth is about ⅖ inch (1 cm.) long and runs from the pulmonary artery near its bifurcation or from the left pulmonary artery to the undersurface of the arch of the aorta a little beyond the point where the left subclavian artery arises from its upper convex surface It serves in the fetus to carry the blood from the trunk of the pulmonary artery direct to the aorta instead of passing into the lungs When, after birth, the lungs are used, the ductus arteriosus becomes obliterated and is found later in life as a cord running to the underside of the arch of the aorta

Aortic Septal Defect (Aneurysm of Sinus of Valsalva). Aortic septal defects consist of (1) a small opening between the aorta and pulmonary artery just above the semilunar valves, and (2) thinness of the septum between the vessels As the result of the thin septum an aneurysm forms of the right sinus of Valsalva or, more rarely, of the posterior sinus. These aneurysms are clinically significant because of a tendency to perforation. In either case the symptoms and signs resemble those of patency of the ductus

The diagnosis is suggested by the sudden occurrence, without apparent cause, of symptoms of progressive heart failure and signs of a communication between the aorta and right side of the heart, a continuous or harsh systolic murmur and thrill.

Death may occur suddenly

Coarctation of the Aorta. There are two forms of coarctation of the aorta, the infantile and the adult The infantile form is characterized by diffuse involvement of the aortic isthmus. Also, this anomaly may be associated with other congenital anomalies, including a patent ductus The adult form is a more localized constriction at or below the insertion of the ductus and usually occurs in boys and men

The heart has a hypertrophied left ventricle. The adult form of coarctation often is associated with a bicuspid aortic valve Congenital subaortic stenosis and aortic insufficiency occur occasionally in cases of adult coarctation, with or without bicuspid valves Miliary aneurysms of the small cerebral vessels are frequent in the region of the circle of Willis

Symptoms are often absent except for those referable to the hypertension in adults The first symptom in a young adult may be sudden hemiplegia.

The objective findings on examination consist of bilateral supraclavicular pulsations in dilated tortuous collateral vessels and in the large subclavian arteries. The collateral vessels are often most noticeable along the inner borders of the scapula and across the scapular area, in the axilla or less often along the sternum or in the epigastrium

The heart is enlarged to the left and downward. There is a moderately loud systolic murmur over the precordium, most intense at the base, but often heard also in the left interscapular region The murmur, sometimes louder in the back than anteriorly, is accompanied by a thrill. There may also be murmurs of aortic stenosis and insufficiency.

There is no palpable aortic pulsation in the abdomen The femoral pulses are weak or impalpable. [illegible] d demonstrable unless

In the a [illegible] extremities, the blood there is hear [illegible] Normally the systolic pressure in [illegible]

blood pressure in the femoral artery is about 20 mm. higher than in the brachial artery. In cases of adult coarctation the brachial systolic pressure is considerably higher than the femoral systolic pressure.

The roentgenologic finding of erosions of the lower borders of the ribs by the large collateral vessels is diagnostic. The erosions may involve a variable number of ribs from the third to the tenth, usually on both sides and in their posterior portion. The erosions are localized and smooth

Preoperative demonstration of the site of the stenosis and its relation to the left subclavian artery is of value to the surgeon. Employment of intravenous cardiography with the aid of diodrast is often effective in revealing the site of occlusion or stenosis of the aorta and often its approximate length and caliber can be estimated In addition angiocardiographic examination may disclose the presence of associated congenital valvular lesions and the state of the collateral circulation, particularly the size of the internal mammary arteries and the aortic branches proximal to the coarctation

The diagnosis of coarctation of the aorta depends on the presence of hypertension, with weak or absent femoral pulse and with blood pressure less in the lower than in the upper extremities. Confirmatory diagnostic data are palpable collateral vessels, a systolic murmur which is as loud in the interscapular region as it is over the precordium, or louder, and roentgenologic observation of erosion of the ribs or defect in the aortic arch

About 1 of every 4 adults who have coarctation attains a relatively normal life span and dies of incidental causes Some may have this disease and it is never known

The commonest complications and causes of death are congestive heart failure, bacterial endocarditis or aortitis, rupture of the aorta and cerebral hemorrhage.

Surgical Treatment. Experience to date suggests that the optimal time for surgical treatment, if this is considered, is between the ages of 6 years and 20 years. In patients more than 20 years of age in many instances the aorta exhibits regional atherosclerosis of sufficient degree to impair the ease and safety of surgical manipulation

Right-Sided or Double Aortic Arch. A persistent right aortic arch or double aortic arch is clinically insignificant It attains clinical importance if physical disturbances arise from its presence

If symptoms appear, they consist of dysphagia and dyspnea by compression of the esophagus or trachea In those in whom the descending aorta crosses to the left, compressing the left recurrent laryngeal nerve, attacks of croup and brassy cough may result When there is a double aortic arch together with an aberrant left subclavian or patent ductus or ligamentum arteriosum forming a vascular ring around the trachea and esophagus, noisy, stridulous breathing, mild dysphagia and chronic cough may occur.

The right-sided aortic arch attains clinical importance when it is to be differentiated from a mediastinal tumor, lymphoma or aneurysm.

The diagnosis is made by roentgenologic examination

Syphilis of the Aorta. *Treponema pallidum* enters the blood stream early in the infection and localizes in the ascending aorta

Between 15 and 25 years often elapse between the onset of the primary syphilitic infection and the appearance of clinical manifestations of cardiovascular disease. The clinical symptoms and signs appear only when the aortic lesions are sufficiently severe and extensive or involve the coronary ostia and aortic valves

Manifested aortic syphilis is most frequent between the ages of 35 and 55 years. The acquired disease, however, has been recorded as late as the age of 70 years and as early as 20 years. Cardiovascular syphilis affects men predominantly. There is a higher incidence of aortic syphilis in Negroes than in whites. There is no

evidence that this is necessarily due to racial susceptibility It is due to the incidence of the disease in this race.

Despite the frequency of congenital syphilis it rarely produces cardio-aortic lesions of the type seen in acquired syphilis.

The gross appearance of syphilitic aortitis is characteristic The distinctive features are the bluish gray plaques without atheroma; the wrinkling and puckering of the intima with a tendency to form parallel grooves in the direction of the long axis of the vessel, and the demarcation of the lesions ending at or before the origins of the vessels of the neck, at the level of the diaphragm or at the origin of the renal arteries. The aorta loses its elasticity and becomes widened and flaccid.

Aortic insufficiency is the result of a widening of the lumen of the vessel and not of direct valvular involvement. There is a destructive inflammation of the aortic wall resulting in dislodgment of the cusp attachments at the commissures

The syphilitic etiology of the valvular lesion is indicated by evidence of syphilis absence of a history of rheumatic fever in childhood, absence of mitral stenosis, *and by the presence of a systolic and diastolic murmur, loudest in the second right* interspace The association of both syphilitic and rheumatic valvular disease may occur

Syphilitic aortic insufficiency is often well compensated for a long time, during which the only symptoms present are palpitation, pounding in the ears or uncomfortable pulsations in the head and neck.

There are frequently no symptoms referable to syphilitic coronary ostial stenosis unless severe involvement is present The diagnosis of syphilitic coronary ostial stenosis is considered when there are syphilitic aortitis and aortic insufficiency, if the patient has angina pectoris. In the absence of evidence for syphilis, angina pectoris is almost always due to coronary arteriosclerosis

On examination there is present a tambour-like second aortic sound, which is not characteristic of syphilis A similar second sound is frequently heard in the presence of aortic atherosclerosis

[illegible] may be considered when there is roentgeno- [illegible] a patient who is less than 40 years old, [illegible] ave hypertension or rheumatic valvular disease In patients aged more than 40 years, who present all the characteristic findings, the diagnosis may be either an aortic arteriosclerosis or a syphilitic aortitis.

Calcification of the Aorta. Calcification of the aorta occurs as a part of a generalized atherosclerosis in middle-aged and aging persons If any clinical manifestation is present it consists of a rough, harsh, basal aortic murmur The murmur arises from interference with the flow of blood into or in the aorta by atheromatous plaques situated in or just distal to the aortic valves.

The calcification is revealed by roentgenologic examination However, many aortas contain calcifications without causing clinical manifestations

Aortic Aneurysm. Aortic aneurysm results from an extensive syphilitic aortitis or atherosclerosis The aneurysms of syphilitic aortitis occur in younger patients (40 to 50 years) while those of atherosclerosis occur in older patients In either case the blood pressure in the vessels serves to dilate the vessel slowly; as a result localized dilatation or sacculation occurs and thus an aneurysm ensues.

Aneurysm of the aorta may remain asymptomatic until rupture and death If symptoms occur, they are those of mediastinal pressure (see Chapter 9). Sudden death is common

The ascending aorta is most frequently involved and is most likely to be associated with both angina pectoris and congestive heart failure. Aneurysm of the ascending aorta, termed *aneurysm of physical signs*, is commonly saccular in type As it enlarges, it extends upward, compressing the right bronchus and lung and the superior vena cava and presenting on the surface of the thorax at the second or

third ribs to the right of the sternum It may also compress the pulmonary artery. A few physicians have seen these visible tumors oozing blood through the skin just prior to their rupture.

Aneurysm of the arch, termed *aneurysm of symptoms*, may compress the esophagus, the left bronchus, the left recurrent laryngeal nerve and the sympathetic nerves and is thus prone to produce symptoms early.

In all of these aneurysms thoracic pain and cough are the commonest complaints. The pain is persistent and may be severe. The dry cough may have a brassy quality and there may be hoarseness (paralysis of the recurrent laryngeal nerve). Soon the cough is associated with expectoration, and more rarely with hemoptysis, both due successively to bronchostenosis, atelectasis and bronchiectasis. Atelectasis, bronchopneumonia, abscess or bronchiectasis may arise not only from tracheal or bronchial compression but also from direct invasion of the lung by the aneurysm. Owing to pressure on the trachea or on a bronchus, inspiratory stridor may develop

On examination by physical means the findings are those of a mediastinal tumor. The heart is not enlarged as a result of aneurysm itself. Inspection and palpation may reveal a pulsation in the anterior thoracic wall in the second or third right interspace, or higher, or to the left. There may be inequality of the pupils and unilateral exophthalmos. Suffusion of the face, neck and upper extremities with cyanosis and edema may be present as the result of pressure on the great veins

A systolic thrill, a diastolic shock, and a tracheal tug downward, synchronous with the heart beat, may be felt The right radial pulse may be diminished in amplitude, delayed or obliterated by partial obstruction of the orifice of the innominate artery A decrease in blood pressure is constant in the arm in which the pulse is decreased

Systolic murmurs are often present over the aneurysm Diastolic murmurs are due to associated aortic insufficiency.

Aneurysm of the *descending aorta* may reach a large size before it produces symptoms When symptoms are present, there are thoracic pain, dyspnea and cough Dysphagia is an occasional symptom resulting from pressure on the esophagus. There is a visible pulsation on the posterior thoracic wall either below and to the left of the left scapula or somewhat higher in the interscapular region.

Syphilitic aneurysm of the *abdominal aorta* occurs in those less than 50 years of age Arteriosclerotic abdominal aneurysm occurs any time from the age of 40 years on The syphilitic aneurysm usually occurs at the level of the celiac axis

The commonest symptom of abdominal aneurysm is pain in the abdomen or back It may be paroxysmal, or constant and boring. There may be root pains extending from the back to the upper part of the abdomen These and other symptoms result from erosion of the vertebrae, or pressure on the spinal cord, gastrointestinal tract, ureter or other abdominal structures. Death is usually caused by rupture of the sac into the peritoneal cavity, gastrointestinal tract or retroperitoneal space Most abdominal aortic aneurysms are asymptomatic.

Examination may reveal an expansile pulsating mass, palpable thrill, and audible bruit, and occasionally a difference in the femoral pulsations. Roentgenologic examination may disclose an abdominal mass with or without calcification and erosion of the anterior vertebral bodies from the eleventh thoracic to the second lumbar

Diagnosis of aneurysm is made by evaluation of the history, physical and roentgenologic findings Roentgenograms of the thorax, and angiocardiograms, if necessary, usually provide the necessary diagnostic data to distinguish aneurysms from other conditions. When aortic aneurysm is suspected, bronchoscopic and esophagoscopic examinations are contraindicated because of the danger of hemorrhage.

The prognosis in syphilitic aortitis is better than in aortic insufficiency, aneurysm or coronary stenosis.

Dissecting Aneurysm of the Aorta. The etiology of this condition is a matter of conjecture. Among the more commonly accepted causes are (1) degenerative changes in the wall of the aorta, (2) congenital defects, (3) mechanical causes, (4) inflammatory reactions and (5) trauma.

The initial symptoms of a dissecting aneurysm of the aorta may be pain and unconsciousness, pain and convulsions, hemiplegia, and vertigo. The symptoms commence as an acute violent pain in the thorax, back or abdomen with a feeling of impending death or annihilation. The pain tends to migrate in steplike fashion from one region of the body to another, suggesting the course of progression of the dissection In contrast to the pain of coronary disease the pain of dissecting aneurysm is not frequently experienced in the arms, but pain and paresthesia are common in the lower limbs. In some instances the pain may never be severe even with rupture.

The neurologic symptoms associated with dissecting aneurysm of the aorta are exceedingly variable and when present result from ischemic necrosis of the brain, spinal cord or peripheral nerves It is difficult to be certain whether the presenting symptoms are of cerebral, spinal or peripheral nerve origin.

The findings on examination depend on the situation of the dissection and the organs affected. Prior to rupture there are no localizing signs After rupture examination is not necessary. Prior to rupture the blood pressure is maintained. The temperature remains normal The leukocyte count is usually elevated.

Examination of the heart may give but little helpful information The presence of a cardiac murmur and the appearance of a precordial rub during the course of the illness are of diagnostic importance The electrocardiogram may show evidence of ventricular strain or other changes, which, however, are not of a specific pattern common to dissecting aneurysm of the aorta. Roentgenologic examination of the chest may reveal helpful information and may even establish the diagnosis. Occlusion of an artery to one of the extremities may be found.

DIAGNOSIS. *The diagnosis of dissecting aneurysm* depends on the sudden onset of severe and usually prolonged and migrating pains and roentgenographic findings of enlarged heart with tortuous aorta which may be dilated and calcified

[illegible] disease cerebral vascular con- [illegible] affections of the spinal cord such as abscess, hemorrhage or myelitis, and [illegible] acute arterial occlusive conditions. Occasionally the symptoms are such that abdominal exploration is carried out and this procedure may not be diagnostic.

Death in the majority of patients is due to an external rupture into one of the body cavities

The prognosis in syphilitic aortitis is better than in aortic insufficiency, aneurysm or coronary stenosis.

Dissecting Aneurysm of the Aorta. The etiology of this condition is a matter of conjecture Among the more commonly accepted causes are (1) degenerative changes in the wall of the aorta, (2) congenital defects, (3) mechanical causes, (4) inflammatory reactions and (5) trauma.

The initial symptoms of a dissecting aneurysm of the aorta may be pain and unconsciousness, pain and convulsions, hemiplegia, and vertigo. The symptoms commence as an acute violent pain in the thorax, back or abdomen with a feeling of impending death or annihilation. The pain tends to migrate in steplike fashion from one region of the body to another, suggesting the course of progression of the dissection. In contrast to the pain of coronary disease the pain of dissecting aneurysm is not frequently experienced in the arms, but pain and paresthesia are common in the lower limbs. In some instances the pain may never be severe even with rupture.

The neurologic symptoms associated with dissecting aneurysm of the aorta are exceedingly variable and when present result from ischemic necrosis of the brain, spinal cord or peripheral nerves It is difficult to be certain whether the presenting symptoms are of cerebral, spinal or peripheral nerve origin.

The findings on examination depend on the situation of the dissection and the organs affected. Prior to rupture there are no localizing signs After rupture examination is not necessary Prior to rupture the blood pressure is maintained The temperature remains normal The leukocyte count is usually elevated.

Examination of the heart may give but little helpful information The presence of a cardiac murmur and the appearance of a precordial rub during the course of the illness are of diagnostic importance. The electrocardiogram may show evidence of ventricular strain or other changes, which, however, are not of a specific pattern common to dissecting aneurysm of the aorta. Roentgenologic examination of the chest may reveal helpful information and may even establish the diagnosis Occlusion of an artery to one of the extremities may be found.

DIAGNOSIS. The diagnosis of dissecting aneurysm depends on the sudden onset of severe and usually prolonged and migrating pains and roentgenographic findings of enlarged heart with tortuous aorta which may be dilated and calcified.

The differential diagnosis includes acute cardiac disease, cerebral vascular conditions, abdominal diseases, thoracic or pulmonary diseases, affections of the spinal cord such as abscess, hemorrhage or myelitis, and finally acute arterial occlusive conditions Occasionally the symptoms are such that abdominal exploration is carried out and this procedure may not be diagnostic.

Death in the majority of patients is due to an external rupture into one of the body cavities

DISEASES OF THE URINARY ORGANS

Diseases of the urinary organs comprise the disorders of the kidneys, ureters and bladder The diseases of the male urethra, which combines the functions of a genital and a urinary organ, are discussed with the diseases and conditions of the external genitalia of the male (Chapter 7).

DISEASES OF THE KIDNEYS

Examination of the Kidneys The kidneys extend from the level of the twelfth thoracic vertebra to the third lumbar vertebra. The twelfth rib passes across each kidney at about its middle.

The position of the right kidney is a little lower than that of the left The right kidney is in contact above with the liver; the left kidney lies adjacent to the spleen. At the medial concave margin of each kidney are the renal vessels as well as the renal pelvis and the renal calyces (major and minor).

Palpation. An imaginary perpendicular line extended from the midclavicular line, at a point 2 fingerbreadths below the costal arch, into the depth of the abdomen will reach the normal kidney, for this organ normally extends for a distance of 2 to 2⅖ inches (about 5 to 6 cm) below the costal margin in the midclavicular line.

On attempting to palpate the kidneys, *bimanual palpation* is employed Thus, on palpating the right kidney, the right hand is placed flat on the abdominal wall in front and, during expiration, presses into the depth. The fingers of the palpating hand are directed upward, the tip of the middle finger reaching a point 2 fingerbreadths below the costal margin on the clavicular line. The fingers of the left hand press the kidney forward from behind while the thumb of this hand holds the liver up (Fig 11-1).

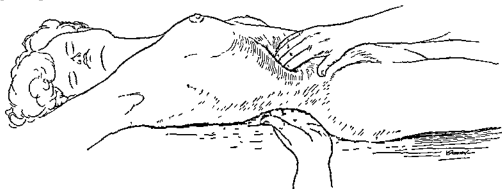

Fig 11-1 Bimanual palpation of kidney.

In addition to the dorsal recumbent position, the lateral, the ventral, the sitting and, especially, the upright postures are employed if needed to delineate the kidney, assuming, of course, that the patient is physically able to take these positions

Perhaps one of the best methods for palpating a kidney is to desire the patient to lie on the back, knees flexed The patient then passes the forearm, *on the side* to be examined, across the back at a right angle to the spinal column with the palm

of the hand downward, and thus lies on the arm and hand, and breathes deeply while the examiner palpates for the kidney.

The normal kidney is not always palpable The palpability of its lower extremity depends on the amount of obesity of the abdominal wall and of the intestine as well as on the degree of distention and on the skill of the examiner. If more than the lower third or the lower half of the kidney is palpable on deep inspiration, the condition is abnormal. When palpable, the surface of the normal kidney is felt as a smooth surface with bluntly rounded margin

The ptosed kidney can be recognized by its absence from its normal position and by the fact that it can be shoved back into its normal position (palpable kidney, floating kidney, wandering kidney). It is 10 times as frequent in women as in men and is usually associated with ptosis of other organs The left kidney is oftener congenitally dystopic than the right The excursion of a ptosed kidney is well demonstrated by employment of intravenous urography

Besides being palpable when displaced, the kidney may become palpable when renal enlargement exists owing to tumors, cysts, hydronephrosis, abscess or tuberculosis. If the kidney is tender, the tenderness often results from renal tuberculosis, pyelonephritis or renal abscess

A kidney may be definitely enlarged and yet not palpable, especially in renal calculus and in renal tuberculosis Obesity or abdominal distention from any cause may interfere with palpation

In deciding whether a kidney is enlarged or whether the structure palpated is an enlarged liver, gallbladder, pancreas, or spleen, the exact topographic situation of the structure is delineated and its relation to the gastrointestinal tract and its mobility are observed. The final decision will have to rest on the findings revealed by the intravenous urogram, ureteral catheterization and functional renal diagnosis. Any pain which may occur in the region of a kidney may be diagnostically perplexing, and for this reason roentgenologic examination of the spinal column is often necessary.

Renal tumors lie rather lower and further to the side of the abdomen than most other tumors, later growing forward toward the anterior abdominal wall so as to fill up the hypochondrium and perhaps displace the liver and diaphragm. Renal tumors lie *behind the colon*

Roentgenology in Urologic Examination The objective means of diagnosis of renal calculus (nephrolithiasis) and of dilatation or contraction of the renal pelves is the intravenous urogram, often supplemented by ureteral catheterization and injection of opaque media Inability of a kidney to concentrate the material used for intravenous urography is a rough and often an inaccurate determination of renal functional activity.

THE EXCRETORY CAPACITY OF THE KIDNEYS The *composition of normal urine,* 24-hour volume, 1,000 to 1,800 ml, specific gravity 1 015 to 1.025, varies insignificantly from day to day. Wide variations in composition may be observed in urine of successive urinations during a single day Urinalysis is made on a well-mixed 24-hour specimen All the urine voided during 24 hours is collected in a clean vessel containing a few drops of a preservative (toluene) and stored in a cool place The bladder is emptied and the urine is discarded before beginning the collection period, the final collection should be made at the end of the 24-hour period

Routine examination of the urine includes macroscopic inspection, determinations of specific gravity and acidity or alkalinity, tests for albumin, sugar, bile, acetone and diacetic acid, and a microscopic examination for cellular elements and bacteria. When bacteriologic study is desired, the specimen is collected by catheterization with the aid of aseptic apparatus and technic.

Physicians have long known the importance of recording the intake of water and

the quantity of urine excreted as a guide in judging the renal functions. The *oliguria* in many cases of acute nephritis, of chronic renal disease associated with dropsy, and of chronic passive congestion of the kidneys has been recognized. So also the *polyuria* resulting from the hard-working remnants of the kidney unable to concentrate urine—fixed specific gravity urine. The comparison of the quantity and the specific gravity of the *night urine* and of the *day urine* is a useful procedure, and one resorted to by many practical diagnosticians.

There are four determinations that should always be made when there is reason to suspect renal disease. (1) determinations of urinary concentrating power (the specific gravity), (2) estimation of proteinuria (albumin), (3) examination of the urinary sediment and (4) analysis of blood for nonprotein nitrogen (blood urea nitrogen). The serum creatinine should be determined if the urea is elevated. If nitrogen retention is present and there is reason to suspect acidosis, a determination of acid-base balance by means of carbon dioxide content or combining power and chloride level is made.

Abnormalities of Excretion of Urine. Oliguria and Polyuria. In *oliguria* the quantity of urine is markedly diminished. When oliguria is associated with albuminuria and cylindruria, especially if hematuria is present, there is organic renal disease, likely glomerulonephritis. In chronic passive renal congestion, oliguria is present with albumin and casts in the urine. These signs clear up when the circulation is restored and the renal stasis is overcome. Oliguria with essentially normal urine occurs in dehydration.

Polyuria (frequency of urination), when persistent, and when associated with urine of low specific gravity, often indicates a chronically diseased kidney and, on rare occasions, diabetes mellitus, or more rarely still, diabetes insipidus. Polyuria may occur in renal amyloid disease and in pyelitis. If the polyuria is associated with high specific gravity of the urine, diabetes mellitus is suspected since this association is rare in renal disease. The common cause of polyuria is nerve tension

Nocturia. Frequent urination during the night is common in renal disease and in prostatism In the latter disorder this is often the first sign noticed by the patient When this symptom is complained of, tests of functional capacity of the kidneys should be undertaken and the prostate examined

Abnormalities in the Excretion of the Constituents of the Urine. *Hyposthenuria.* In hyposthenuria the specific gravity is low, no matter what quantity of urine is passed It would appear that, in many of these conditions, the kidney is unable to secrete a urine of greater concentration

Hypazoturia. In some cases of renal disease the kidney is unable to eliminate nitrogenous substances adequately. This condition is often met with in association with high blood pressure without uremic symptoms and without edema. The nonprotein nitrogen of the blood is increased in amount Sodium chloride and water may be excreted fairly well in the urine.

Hypochloruria. Hypochloruria may be associated with edema Often the nitrogenous substances may be well eliminated, while sodium chloride is retained. In such cases addition of sodium chloride to the food leads t
an accentuation of the oliguria and an increase in the
chloride is retained, water accumulates in the tissues
In other cases relatively more sodium chloride may be retained than corresponds to physiologic salt solution, the edema in such cases may be slight, so that it is recognizable only by a slight increase in the body weight. In retention of water and salt extrarenal factors, such as cardiac decompensation and starvation, may be responsible.

The Low Salt Syndrome. The term low salt syndrome has been suggested by Schroeder. This syndrome or similar conditions have been observed and described previously, but the term low salt syndrome seems appropriate in order to unify data.

The syndrome appears to be a state of renal insufficiency dependent on a dis-

turbance of the normal concentration of sodium chloride in extracellular fluids. It is not dehydration, because large stores of fluids may be present It is not dependent on alkalosis, for the carbon dioxide-combining power of the blood may be altered only slightly. It can be initiated by depleting the body of sodium chloride through the use of either mercurial diuretics or other measures, by producing a large discrepancy between the intake and the output of fluid, or by excessive loss of salt through abnormal routes. It is often reversible by restoring the concentration of sodium chloride in body fluids to normal, a procedure which can cause diuresis and a return of renal function to higher values. It may accompany, but is not always dependent on, circulatory insufficiency; it is usually associated with prior renal disturbance, either functional or organic

It is probable that the excessive postoperative use of dextrose solution in water without sodium chloride contributes to renal insufficiency and initiates the low salt syndrome in elderly patients or in those who already have some renal disturbance of minor degree

SYMPTOMS The first symptoms observed by the patient or the members of the family or nurses are drowsiness, weakness and lethargy. There are a loss of appetite, nausea and occasionally vomiting In rare instances, particularly in prostatism with mild renal insufficiency, there may be symptoms of intestinal obstruction. The normally occurring muscular cramps in the low salt syndrome involve the muscles of the anterior abdominal wall as well as those of the back and legs and elsewhere. If the attention is directed to the abdominal distention and the cramps of the abdominal muscles to the exclusion of the other cramping muscles, too much emphasis may be placed on the abdominal symptoms which simulate intestinal obstruction

A history of a successive depression of urinary volume beginning from a few days to a week prior to the onset of symptoms is most helpful diagnostically. If the patient is one who knows his usual body weight, it will be evident that a gain in weight has occurred since the suppression of urinary output

EXAMINATION The physical findings vary and depend on the original illness, whether cardiac, postoperative, or renal disease, or prostatism There is a depression of urinary chlorides to negligible quantities which will not increase after injection of mercurial diuretics The concentrations of chloride and sodium in the plasma are low. An elevation of the concentration of nonprotein nitrogen in the blood is constantly present.

DIAGNOSIS. The diagnosis depends on awareness of the possibility of the condition and the finding of little or no chloride in the urine with a greatly decreased level of chloride in the plasma.

The Excretion of Abnormal Substances in the Urine. The list of substances which may appear in the urine which are present or found in traces in the normal urine is an extensive one Enumeration of these substances will not be made here since they are given in other parts of this text Reference should be made to discussions of diseases of metabolism (Chapter 22) and of poisoning by organic and inorganic chemicals (Chapter 19)

It is appropriate here to mention orthostatic albuminuria, cylindruria, hematuria, pyuria and bacteriuria, idiopathic hematuria and nonparasitic chyluria

Orthostatic Albuminuria. This albuminuria appears as the true or idiopathic form, as an albuminuria with an orthostatic response, and in association with latent and chronic glomerulonephritis

In the *true or idiopathic orthostatic albuminuria*, albumin occurs in the urine when the patient is in the erect position A specimen of urine excreted while the patient is in the lying position is free of albumin Some of these patients, however, may excrete a small amount of albumin immediately after lying down

Albuminuria with an orthostatic response is characterized by the presence of

albumin with the patient in any position, but in greater amounts while in the upright position.

In *chronic latent glomerulonephritis* there is a history of acute nephritis which has subsided and of albuminuria which has persisted. This condition differs from the usual orthostatic albuminuria by the excretion of traces of albumin during the night or when in the reclining position.

In all who have albuminuria, renal disease of some sort is present The nature of the renal abnormality in idiopathic orthostatic or true orthostatic albuminuria is not known. A patient who has a true orthostatic albuminuria is no more likely to have renal disease than a normal person In all the rest of those who have an orthostatic element in the excretion of albumin in the urine, there will be usually a normal response to all of the tests of renal functional activity.

There are no symptoms The albuminuria is discovered when the patient takes a routine physical examination, such as an examination for life insurance or for military service or entrance to a military institution.

On examination these patients are often described as tall and as having an increased lumbar lordosis This bodily build is by no means constant; any somatic type may be affected. The results of physical examination, except in the group who have chronic glomerulonephritis, are essentially negative

In the examination for orthostatic albuminuria, have the patient empty the bladder on retiring at night. The first specimen in the morning is collected, and this should be free of albumin. A second or a third specimen is obtained after the patient has been standing or walking for a half hour or more, and is examined for albumin. This specimen should contain albumin of grade 2 or more, graded on the basis of 1 to 4.

The diagnosis of orthostatic albuminuria is made when the results of general physical examination, including the blood pressure, microscopic examination of the urine and ophthalmoscopic examination are all within the limits of normal and the albuminuria occurs only when the patient is active and in the upright position.

Cylindruria. Urinary casts (cylindruria) are designated as hyaline, epithelial or granular, and as blood casts Hyaline casts, the commonest variety, are believed to originate in three ways. (1) from the renal epithelium itself, (2) from the coagulation of transuded plasma or (3) as an excretion of living tubular epithelium Epithelial casts may arise from the desquamation of the original lining of the renal tubules or from the shedding of newly generated renal epithelium. Blood casts are formed within the tubules from blood arising from a ruptured capillary, nearly always one of the glomerular capillaries

Hematuria, Pyuria and Bacteriuria. Blood, pus or bacteria may occur in the urine as the result of renal disease, but more frequently they have an extrarenal origin, such as from the renal pelves, ureters, bladder and urethra.

Renal hematuria indicates diseased glomeruli The glomerular disease may be a diffuse glomerulitis, or it may be the result of a focal embolic injury, or an infection associated with bacteremia, or from high fever

Idiopathic hematuria occurs in cases in which no discernible reason for the bleeding can be found.

Pyuria is much more often due to inflammation of the urinary passages than to a purulent inflammation of the kidney itself, though in surgical kidney and in tuberculosis of the kidney pyuria of renal origin is met with

Bacteriuria may have its origin in bacteria which pass through the injured renal filter. However, the usual cause is infection from below through the urethra or, sometimes, by direct passage from the rectum into the bladder.

Nonparasitic Chyluria. If the lymph channels are obstructed by inflammatory, suppurative or neoplastic disease in the lower part of the thoracic region or in the upper part of the retroperitoneal region, and if the dilated lymphatics rup-

ture into a kidney or a renal pelvis, chyluria ensues. Spontaneous chyluria may occur in the absence of any serious disease. Chyluria causes symptoms when the chylous masses obstruct urination The urine is milky with fat globules. The kidney and ureter which are involved are determined by ureteral catheterization, and the lymphatic connection is demonstrated by the retrograde urogram The Babcock test for fat in the urine may reveal the presence of as much as 1 or 2 per cent of fat

These patients may have ureteral colics from obstruction of the ureters by clots of the chylous urine. Likewise the urethra in men may become obstructed from clots Vesical symptoms may be severe until the clots are removed by endoscopic methods. If the condition progresses, these patients fail rapidly and die from innutrition

Tests of Renal Functional Activity. Richards and his associates demonstrated by direct analysis that the glomerulus in the frog is a mechanical filter and that the glomerular filtrate is a simple filtrate It seems likely that these same conditions prevail in man The maintenance of the composition of the extracellular fluids with its remarkably constant volume and composition of potassium, sodium, chloride and other electrolytes is accomplished by selective resorption by the renal tubules of exactly those constituents of the glomerular filtrate in the correct amounts to maintain a uniform composition of *the extracellular fluids of the body The constant maintenance of these uniform values* is made possible by the large total volume of blood flowing through the kidneys per minute (more than 1 liter) This is about one fifth of the minute volume output of the heart

Renal functions receive stimuli from other parts of the body, some of them probably in the form of hormones The pituitary body secretes an antidiuretic hormone that stimulates reabsorption of water Adrenal cortical hormones regulate the activity of the tubules with regard to reabsorption of sodium and potassium

The functional condition of the kidneys can be estimated by the specific gravity of the urine and by the urea and other clearance tests. Inability of the kidneys to concentrate the urine, as revealed by specific gravity tests, is the most practical and perhaps the most sensitive test of renal functional activity

Renal disease is not the only condition that can cause a decided decrease in renal function Any condition that causes a decrease in blood flow through the kidneys will cause a corresponding decrease in renal function Renal failure proceeds from (1) destruction of the nephrons by disease, as in chronic nephritis; (2) cessation of the renal blood flow from any cause, either by mechanical obstruction, as in sclerosis or thrombosis, or by excessive vasoconstriction or decrease in blood volume as is observed in shock, (3) toxic damage to the tubules, such as occurs in poisoning by nephrotoxic substances or by prolonged and severe ischemia, (4) fall in blood pressure in the glomeruli below 50 mm of mercury which results in a cessation of filtration and in anuria

It seems desirable to enumerate some of the special methods of testing clinically the functional ability of the kidneys Tests of renal function are performed under controlled conditions. Through these tests attempt is made to evaluate the ability of the kidneys to purify the blood by excreting (1) water, (2) the normal urinary solid constituents and (3) substances foreign to the body introduced especially for testing purposes In these studies special attention is paid to (a) the time required for the appearance of the excretion of the substances under test, (b) the length of time taken after excretion of the substance begins until all that is to be excreted has passed out, (c) the quantity of the introduced substance which can be recovered from the urine during the period of the test, (d) the concentration relations of the substance in the urine and (e) the relations between the amount of the substance in the blood and the amount excreted in the urine at the time of the test

Of the methods which determine the excretion of water and the excretion of total solids and of electrolytes, the determination of the specific gravity of the urine is most valuable diagnostically. If the specific gravity of a single specimen of

urine is more than 1.020, and if the urine is not heavy with albumin, generally the renal function is adequate for most immediate needs. However, if more information is required, it is well to use one of the procedures for concentration of the urine.

THE CONCENTRATION TEST OF ADDIS AND SHEVKY. 1. The patient abstains from fluid approximately 24 hours (after breakfast of one day until arising the next day).

2. Urine voided during the first 12 hours is discarded.

3. Urine voided during the last 12 hours (8 P.M to 8 A.M) is collected and the specific gravity determined. With restriction of fluid the normal kidney can excrete a urine of specific gravity of 1.025 or higher.

The specific gravity is a measure of the concentration of the dissolved constituents and is an expression of the contributions of each of the individual components of the urine. In a person who has normal kidneys and who is eating a mixed diet, the dissolved materials which are responsible for the specific gravity of the urine are the chloride, urea, sulfate, phosphate, bicarbonate and creatinine, named in the order of maximal contributions of each substance. The remainder of the specific gravity is the result of the contributions of organic compounds besides urea

Urines of low specific gravity from normal kidneys are the result of dilution. In advanced renal insufficiency the specific gravity of the urine becomes fixed In both dilute urines and those with a fixed specific gravity the relative composition is not altered from normal

In tubular disease or when there is reduction in renal mass, the specific gravity falls proportionately and finally becomes fixed at approximately 1 010 When the urine is heavy with albumin, correction for the albumin should be made by subtracting 0 003 from the specific gravity for each 1 gm. of albumin per 100 ml of urine.

In contrast to the concentration tests are those of dilution of the urine In these dilution tests the specific gravity of the urine should go down to 1.005 or less The capacity of the kidney to form a dilute urine parallels its concentrating powers sufficiently closely that dilution tests are seldom necessary. However, if a dilution test is desired, the test devised by Fishberg is a desirable one

THE DILUTION OR WATER FUNCTION TEST OF FISHBERG 1 Omit breakfast For dinner and supper give the usual routine nephritic diet or the diet to which the patient has been accustomed. Permit one glass of water after supper.

2 At 8 A M have the patient empty the bladder and give 1,500 ml of water. Discard the urine

3 Collect urine in specific containers at hourly intervals, beginning at 9 A.M and ending at 12 M, making four specimens in all

4 Carefully measure and take the specific gravity of each specimen

Methods which determine the power to excrete specific chemical substances, for instance phenolsulfonphthalein, have been and still are profitably employed in renal diagnostic work Forty to 60 per cent of the dye is excreted during the first hour and 20 to 25 per cent is excreted during the second hour by normal kidneys

THE UREA CLEARANCE TEST 1 This test is usually performed in the morning, since excretion is less likely to fluctuate during this period than at other times of the day, but, if necessary, it may be done at some other time, provided at least five and a half hours have elapsed since the preceding meal It is advisable for the patient to rest in a reclining position

2 The patient is requested to drink a glass of water and immediately thereafter empty the bladder This specimen is not saved but the time of voiding is carefully recorded.

3. At the end of approximately one hour, the patient again voids, the time is accurately recorded and the specimen saved At about this time (± 15 minutes) blood is withdrawn from a vein (2 to 3 ml is sufficient).

4. A second glass of water is then taken

5. One hour later the patient again completely empties the bladder The time is again accurately recorded and the specimen saved

The two specimens of urine and the blood are then sent to the laboratory for analysis

In Van Slyke's urea clearance test the average normal adult excretes the amount of

urea contained in 60 to 95 ml. of blood per minute The average excretion is the urea in 75 ml. of blood per minute. Slight impairment of excretion of urea is that amount in 30 to 60 ml. of blood per minute Moderate reduction is 20 to 40 ml Maximal reduction is the excretion of the urea in 10 ml. or less of blood per minute This test is inaccurate in edema with relative oliguria. It may be abnormally increased during fever in young persons.

THE XYLOSE TEST. On the supposition that xylose is not metabolized, and on the fact that inulin is excreted by the glomeruli only, clearance tests employing these substances have been devised but not commonly used.

THE PHENOLSULFONPHTHALEIN TEST. The phenolsulfonphthalein test has been widely used as a test of renal functional activity. In places where laboratory facilities are limited and when economy to the patient is desired, it can be employed, and if extreme dehydration or edema is not present, it may give the desired information in regard to renal function.

1. Give the patient 300 to 400 ml (about 2 glasses) of water to promote diuresis. Smoking and the taking of coffee or tea should be forbidden at least 2 hours prior to, and during, the test.
2. Twenty minutes later have the patient empty the bladder and discard the urine. In case of necessity catheterize
3. Then inject intramuscularly exactly 1 ml of the sterile phenolsulfonphthalein solution If there is general edema, the solution should be injected intravenously.
4. Exactly one hour and 10 minutes later have the patient empty the bladder (or catheterize) and save the urine.
5. Exactly one hour later (2 hours and 10 minutes after the injection) have the patient empty the bladder (or catheterize) and save the urine

Send both specimens to the laboratory for an estimation of the phenolsulfonphthalein in each

In preoperative examination before any major surgical procedure there are measured (1) the amount of urine, (2) the acidity, (3) the specific gravity and (4) the concentration of the blood urea. If the operation is to be made on a kidney and the function of the other kidney is in doubt, the phenolsulfonphthalein output of each kidney is ascertained after intramuscular injection of a given amount of this chemical; in some cases *0 01 gm of phlorhizin is injected subcutaneously and the amount of sugar excreted* by each kidney is subsequently determined

INORGANIC SULFATES The retention of inorganic sulfates as manifested by an increased concentration of these substances in the plasma or serum often occurs before there are detectable changes in the values for the blood urea or changes for the clearance tests The normal range of inorganic sulfates (SO_4) is from 2.5 to 5 mg per 100 ml of serum

NONPROTEIN NITROGEN AND BLOOD UREA The concentration of the total nonprotein nitrogen in the blood of normal persons in the postabsorptive state varies between 25 and 40 mg per 100 ml After an excessive ingestion of protein a concentration of 45 mg per 100 ml of blood may be present The nonprotein nitrogen comprises the nitrogen contained in the urea, ammonia, amino acids, uric acid, creatine and creatinine, of which the urea is the most important

The concentration of blood urea in normal persons varies from 10 to 50 mg. per 100 ml of blood if the blood is drawn during the postabsorptive state The range of blood urea (from 10 to 50 mg per 100 ml of blood) corresponds to 5 to 23 mg of urea nitrogen per 100 ml of blood

In routine clinical work the foregoing values for nonprotein nitrogen and for blood urea may be considered indicative of normal renal functional activity in the [illegible] is likely [illegible] a history [illegible] erformed [illegible] who have hypertension or who have a history of nephritis and have albumin in the urine.

Hyperazotemia occurs in renal insufficiency and from extrarenal causes In view of the extrarenal factors the measure of the concentration of urea in the blood

alone cannot be entirely relied upon for the detection of slight renal insufficiency, for often the concentration of the blood urea will reach 100 mg. per 100 ml. of blood during dehydration without there being any detectable impairment of renal functional activity If the possibility of the presence of these extrarenal factors which may cause an increase in the concentration of blood urea be kept in mind, and ruled out, the retention of nitrogenous substances is significant. It does not matter whether the concentration of nonprotein nitrogen or of the urea nitrogen is determined; the information is essentially the same when interpreted with a knowledge of the respective normal ranges of concentrations in the blood.

Functions of Individual Kidneys. By means of ureteral catheterization the urine from each kidney can be collected separately, and thus the amounts of urine, and also the solid substances, excreted by each kidney during a given time can be compared The procedure is of especial value in surgical cases in which one kidney is so seriously diseased as to demand a consideration of nephrectomy. Before performing nephrectomy, however, the surgeon desires to assure himself (1) that the other kidney is present and (2) that it is still healthy enough to keep the patient alive

The Reaction of the Urine. The reaction of the normal urine is acid However, normal urine with an alkaline reaction may be excreted for short periods of time without changes in health

The reaction and the degree of acidity (pH) of the urine are often helpful in giving clues regarding the character of bacteria causing an infection. Moreover, there is a form of urinary hyperacidity of neuropathic origin in which there is no infection, though the symptoms may simulate those of cystitis

BICARBONATE AND RENAL REGULATION OF ACID-BASE BALANCE The important renal function in the regulation of acid-base balance is made manifest by the reabsorption of base (bicarbonate), the excretion of acid phosphate and other acidic anions, the synthesis of ammonia and the formation of citric acid The quantitative relationship between plasma bicarbonate concentration and the rates of tubular reabsorption and urinary excretion of bicarbonate indicates that there is a definite renal threshold for bicarbonate of approximately 25 millimols per liter of plasma Below this concentration of bicarbonate in the plasma the bicarbonate in the glomerular filtrate is reabsorbed at a rate which may be expressed as a linear function of the plasma concentration Under ordinary conditions in which there is a need for conservation of base, for practical purposes all of the bicarbonate (99 95 per cent) is reabsorbed. In contrast, in excess of base, bicarbonate excretion may be almost as nearly complete. The renal reabsorption and excretion of bicarbonate therefore constitute a primary mechanism whereby the body may defend itself against either loss or increase of its alkali reserve and thus may maintain its acid-base balance

These mechanisms are mentioned here because of their importance in maintenance of normal reactions of the urine

Renal Failure Years ago MacCallum taught that in renal failure there is a loss of functional units, the nephrons of the kidneys. This loss may be incident to degeneration of the glomerulus first, followed by secondary degeneration of the tubule, or the disease may begin in the tubule When a sufficient number of nephrons are destroyed, there is an ensuing hypertrophy of the remaining glomeruli and tubules Recently Platt has made observations on animals and has reaffirmed that in renal failure some nephrons

is increased.

The concentrating capacity of the normal kidney has a limit When the kidney is sufficiently diseased, it can excrete either a small volume of concentrated urine or a greater volume of dilute urine. In many instances, as renal failure approaches, it seems that a greater volume of dilute urine (polyuria) takes place. Platt has expressed the belief that a polyuria and a fixed specific gravity of urine in renal failure are evidence of

normally functioning nephrons, each one of which is excreting an excess of urea and osmotic substances An increase in the concentration of the blood urea in the presence of polyuria implies that the compensatory mechanism manifested by a polyuria is no longer an effective compensatory mechanism.

A diuresis may be induced from the ingestion of water In the normal kidney or in the failing kidney the diuresis is due either to a diminished reabsorption of water by the normal tubules or to an increased secretion by the hypertrophied tubules An assumption of this particular sort of function in the renal tubule does not deny the established fact of glomerular filtration but it does question the ability of the glomerulus to perform the whole task of forcing fluid and electrolytes out of the glomerular capillaries and pushing these substances down the renal tubule It is more reasonable to assume that a tubular secretion of some fluid is economically desirable and hydrostatically possible.

In renal failure due to intrinsic causes there is an inability to excrete an adequate volume of urine to carry away the metabolic waste products and excesses of electrolytes Such an inability may be due to an insufficient number of functional units even though remaining functional units have hypertrophied as a compensatory mechanism.

As renal failure develops, there is evidence of disturbances of both filtration and absorptive function of the kidneys

Edema of renal origin appears to depend on injury to the capillaries in the renal glomeruli and similar changes in all of the small blood vessels all over the body, resulting in their increased permeability Acute weakness of the myocardium may precede or follow these vascular changes (see Theories of Heart Failure, Chapter 10).

The edema of renal origin begins very often in the face, especially about the eyelids, and is thus in contrast with the edema in chronic heart disease, in which the influence of gravity and of distance from the heart is an important factor in the distribution of the edema to distant dependent parts, such as the legs, if the patient is ambulatory, and the back, if confined to the bed

The *edema which occurs in the later stages of vascular hypertension* is rarely due directly to the renal lesion itself, but may depend on a failing myocardium,, and is therefore a true *stasis edema* rather than a renal edema A true renal edema may occur, of course, if the vascular disease seriously injures the kidneys or if an acute nephritis is superimposed on the chronic glomerulonephritis

In many forms of renal disease, but by no means in all, the blood pressure is high, and this *arterial hypertension* is associated with *hypertrophy of the left ventricle*, thus a maximal blood pressure of 160 to 200 mm of mercury or more, associated with dislocation of the apex beat downward and laterad, is common

Uremia signifies the presence of excessive amounts of urinary constituents in the blood Excessive urinary constituents in the blood may arise from extrarenal causes as well as from renal disease *Extrarenal hyperazotemia* is an example of an extrarenal cause for an apparent retention of urea This condition is commonly observed in obstructions of the pylorus and of the upper portion of the small intestine. These extrarenal hyperazotemias in part result from dehydration and the loss of sodium chloride from vomiting, from aspiration through suction tubes, or from diarrhea

Uremia occurs in acute and chronic forms, and the symptoms therefore vary widely A large number of symptoms have been grouped under the heading of uremia, but rarely are all of them present in any one patient In uremia, symptoms referable to the nervous system are common and are the most prominent. However, uremia also affects the respiratory, the circulatory and the digestive systems

The origin of the uremic symptoms is not clear The idea that the concentration of urea in the blood is responsible has been abandoned

A *complete and sudden suspension of the excretory functions of both kidneys* resulting in anuria may occur spontaneously or after ligation of both ureters or removal of a solitary kidney by surgical operation Under such circumstances symp-

toms like those which occur in chronic uremia are not present. At first there are no symptoms to suggest the impending disaster, but after a few days the patient grows weak and becomes sleepless, and toward the end of a varying period of about 10 days he complains of dryness of the mouth and drowsiness Muscular twitchings set in, but convulsions do not occur The pupils are contracted The sensorium usually remains clear until the end, though some patients have terminal delirium The temperature is subnormal Headache, vomiting and the ammoniacal odor of the breath so characteristic of uremia do not appear in obstructive suppression of urinary excretion

One of the most constant symptoms in uremia, and often the first to be complained of, is headache, sometimes so severe that morphine may be required for its relief

Uremic dimness of vision and uremic amaurosis may occur independently of retinitis, choked disk, the concentration of blood urea and the degree of acidosis Scotomas may or may not be present. Tinnitus aurium and dizziness are common symptoms

Convulsions are rare, but they are a part of the nervous symptoms Uremic convulsions usually are preceded by headache, vomiting and dimness of vision and occasionally by an aura The convulsions begin by an initial tonic stage followed by clonic spasms and tongue biting The pupils are usually dilated, rarely contracted After the fit the patient may remain in coma for a time, or there may be simply a period of somnolence Repeated convulsions are common In many of these cases death occurs during a fit, if recovery takes place, transient to temporary blindness is a common sequel

In uremia temporary paralyses are common Uremic hemiplegia and uremic aphasia are well known, they are probably due to edema of the brain, for at necropsy no gross lesion is demonstrable except in the cases in which actual vascular lesions have complicated a uremic state

Aside from the coma which follows a uremic convulsion, patients suffering from uremia sometimes are subject to coma that develops gradually after a period of drowsiness and mental torpor Hyperkinetic phenomena such as twitchings and local spasms may accompany the coma. The breathing is often of the Cheyne-Stokes type, but such breathing is not diagnostic Instead of complete unconsciousness, they may be delirium, variable in degree Sometimes outspoken maniacal seizures are present or, in the more chronic cases, pathologic ideas, melancholic, religious, erotic or persecutory, may develop

The presence of anorexia, nausea, vomiting and hiccough are common symptoms Sometimes there is diarrhea Whether or not the stomatitis and the ulceration of the intestine, so often found at necropsy on subjects who died of uremia, are due to the uremic intoxication or to complicating infection is not known

In uremic states inflammations of the serous membranes are common, for instance, pericarditis and pleuritis Peritonitis, however, rarely occurs. Often none of these is diagnosed clinically.

Myocardial insufficiency, hypertension, paroxysmal dyspnea and perhaps congestive heart failure are not uncommon in uremia.

At the onset of uremia there is a diminution in the amount of urine excreted, without a change in urinary specific gravity, which is low. The concentration of the total nitrogen of the urine and the urea nitrogen is decreased The acidity of the urine is increased, and the output of ammonia in the urine is relatively high The excretion of sodium chloride may not be changed Owing to the increased concentration of urea in the blood there is an increased excretion of urea through other emunctories, especially through the sweat. Fine crystals of urea may be visible on the skin of a uremic patient who has a dark complexion

The *diagnosis* of uremia is obvious if the history of the patient is well known so that appropriate chemical studies of the blood can be made (increased concentration of urea and nitrogen in the blood). The diagnosis of uremia may be difficult in those manifesting convulsions, paralyses, or coma when first seen. Likewise a patient manifesting some one particular symptom, such as persistent vomiting, hiccough, or Cheyne-Stokes breathing, in the absence of other symptoms, may not be recognized as uremic at first, though the further course of the disease and determinations of the concentration of urea and nitrogen in the blood will make the condition clear. Uremic convulsions may occur in a patient in whom the concentration of blood urea is less than 100 mg per 100 ml of blood.

The outlook in uremia is always doubtful The patient may recover from an acute attack, and if the renal disease is an acute nephritis and ends in recovery, there may be no recurrence However, when a uremic attack has occurred in the course of a chronic renal disease, even though the patient recovers from the attack in which he is first seen, this will, sooner or later, be followed by others, and death will ensue.

In those who are severely dehydrated (extrarenal hyperazotemia), and who have moderately good renal reserves, appropriate parenteral administration of fluids will often give immediate relief (see Intestinal Obstruction, Chapter 13).

Congenital Malformations of the Kidneys. The kidney, the ovary and the mullerian duct arise from the urogenital ridge If there is a defective development, there may be an associated absence of the kidney, the uterus, and the vagina, and there may be a rudimentary ovary, all on the same side Certain irregularities of development may result in a supernumerary kidney either entirely separate (free) or fused with the homologous kidney When the supernumerary kidney is separated from the other kidney, its ureter may be separated from the other ureters and have a separate opening into the bladder. It often unites with the adjacent ureter before reaching the bladder A much rarer condition is duplication of both kidneys and ureters, which does occur occasionally. However, any number of kidneys from one to four may be present

The kidney usually conforms to the usual size, shape and form Its variation in size is often dependent on the health of the opposite kidney Physiologic or compensatory hypertrophy is the commonest cause of unilateral renal enlargement

There are many inconsequential variations in shape, in normal kidneys, such as superficial fetal lobulations, and the elongated and rounded kidney.

The variations in form resulting in fusion of the opposite kidney constitute *horseshoe kidney* A horseshoe kidney is one of the commoner renal anomalies, although it is not so common as double kidney The opposite kidneys may be connected with each other at the upper or lower poles Fusion of the lower poles is the usual type There are, however, various types of fusion of the isthmus

Horseshoe kidneys need not cause symptoms Hydronephrosis is particularly common in horseshoe kidney, owing to aberrant blood vessels, fascial bands or stricture. Infection often follows

The two kidneys may form an elongated mass, divided by a fissure or by deep lobulation Each kidney has its own pelvis, calyces and proximal ureter. The ureter from each kidney may remain distinct and open separately into the bladder. In other instances the ureters from the two fused kidneys may unite at any point in their course and have a common ureteral orifice in the bladder Double fused kidneys are often poorly developed The calyces are fewer than normal It is postulated that double fused kidneys become pathologic from ureteral obstruction due to vascular anomalies, aberrant vessels or fascial bands which produce hydronephrosis, infection and the formation of stones

In the presence of a unilateral fused kidney, often there is some defect in the opposite half of the urinary organs

The *ectopic kidney* and the *movable kidney* are examples of anomalies of position. An ectopic kidney is misplaced congenitally, and there are often other evi-

dences of anomalous renal development The movable kidney, however, a normal kidney in ptosis, the abnormal position generally being acquir

The ectopic kidney is fixed and has a short pedicle and a short ureter. supply is derived from the nearest source arising and passing directly to t kidney. The vascular pedicle and ureter are far too short to admit the presun the kidney was ever situated normally.

The ectopic kidney may be congenitally hypoplastic and associated with o opmental lesions in the urinary tract There may be associated anomalies in ductive organs—especially in connection with the müllerian ducts such as no the mullerian ducts—from bicornuate uterus to complete nonunion, with uterine tubes, absence of uterus, and absence of vagina

When the ectopic kidney is lower than normal, and on the same side as orifice in the bladder, the condition is called simple ectopy, in contrast wi *ectopy, in which the ectopic kidney is on the opposite side from the opening of* into the bladder.

The ectopic kidney may be separate from the normal kidney or may be f it as in fused ectopy. A fused ectopy may constitute all of the renal tissue t possesses

If renal function is adequate and if the ectopic kidney remains healthy, the is compatible with renal health However, in ectopic kidneys pathologic dis such as hydronephrosis and infection are likely to develop When the ectop obstructs the birth canal, obstetric complications such as dystocia, rupture of t and death may ensue An ectopic kidney in the pelvis, discovered on palpa resemble an ovarian cyst, uterine myoma, or retroperitoneal sarcoma Urograp be used in all cases of obscure pelvic tumors

The diagnosis of all of these malformations of the kidneys can be es by intravenous urography, pyelography and cystoscopy However, the may not be suspected and then may be discovered accidentally during a operation for a condition suspected of being a pelvic tumor associated internal genitalia Unless it can be established that the other kidney is pre capable of sustaining life, the ectopic kidney should never be removed

Congenital anomalies of structure include such conditions as hypopla genital hydronephrotic atrophy and congenital cystic kidney. These conditic lap with others such as ureteral obstruction and renal tumors so that differ on clinical data cannot be made

Atypical vessels, aberrant arteries that go to the upper or the lower common in kidneys that are normal otherwise Such aberrant vessels, w pass to the lower pole, may kink the ureter as *the kidney changes its positic* may thus cause renal pain and hydronephrosis.

The Heart and Blood Vessels in Relation to Renal Disease. In *gl nephritis* there may be hypertension, cardiac enlargement, and congesti failure.

Hypertension is present in one half of those who have acute diffuse glo nephritis and occurs at the onset of the disease. The rise in blood pressure always moderate

Cardiac enlargement in nephritis is mild. It appears early, probably w first week or two of the disease In the presence of pronounced congesti failure the heart is greatly enlarged. If recovery from the congestive failure a return to normal cardiac size is the rule. Occasionally cardiac enlargem sists despite normal blood pressure In these enlarged hearts there is hype as wall as dilatation of the left ventricle

The cardiac enlargement may be present in the absence of hypertension instances *the degree* of cardiac enlargement is out of proportion to the m vation in blood pressure and its brief duration Both cardiac hypertrophy and ... attributed to myocarditis associated with glomerulonephr

Heart failure usually begins with tachycardia, muffled cardiac tones, an apical systolic murmur, gallop rhythm and rales at the bases of the lungs. In some instances the failure is characterized by a sudden onset of dyspnea and orthopnea, progressing to acute pulmonary edema. Pleural effusion is common and is part of the general anasarca.

Low or inverted T waves in lead I and in the precordial leads are common electrocardiographic changes Prolongation of the P-R interval and the Q-T interval may be present.

Chronic Passive Renal Congestion. This is a common condition It is in the end a congestive failure of the kidney It occurs under all conditions in which there is chronic passive congestion of the organs due to venous stasis, thus it follows (1) cardiac decompensation, no matter what its cause Less frequent causes of stasis in the renal veins are (2) obstructions to the inferior vena cava above the level of the renal veins and (3) pressure on the renal veins themselves from any cause

In cardiac decompensation two factors are important (1) decreased arterial flow into the kidney and (2) lessened venous outflow from the kidney A decreased arterial flow causes glomerular congestion, with excretion of albumin Lessened venous outflow causes engorgement of the kidney In cardiac decompensation the entire kidney is engorged The kidney becomes somewhat enlarged, is dark red, and is firmer than normal Degenerative changes occur in epithelial cells of the renal tubules, but there are no actual inflammatory lesions

The urine is scanty and of darker color than normal It is turbid and concentrated, and deposits a red sediment in the cold The specific gravity may at first be high A moderate amount of albumin is present Casts are present, but they are relatively few since there is no marked degeneration or destruction of the renal epithelium A few erythrocytes and leukocytes are usually to be found in the sediment

When functional tests are made, the phenolsulfonphthalein output is usually reduced, and the concentration of urea nitrogen is normal at first If the congestion continues, the concentration of urea nitrogen increases, though not to so great a degree as is observed in nephritis with the same degree of albuminuria

Chronic passive renal congestion is not confused with an early nephritis because there are signs of myocardial insufficiency present such as dyspnea, cyanosis, edema, palpable liver, enlarged heart, and often cardiac arrhythmia. Present in these patients are the possibility and the probability of an accompanying renal failure too If cardiac compensation is restored and there is no renal damage other than chronic passive congestion, the urine will become clear again, more abundant, of higher color, and free from protein and casts Should the urine, however, remain abnormal, there is coexisting renal damage

Diffuse Arteriolar Sclerotic Renal Disease. Chronic renal atrophy resulting from diffuse sclerosis of the small organ-arterioles of the kidneys is characterized clinically by polyuria, slight albuminuria and cylindruria, and chronic arterial hypertension with cardiac hypertrophy Death occurs often after many years of fairly good health, from cardiac failure, cerebral apoplexy, uremia or a terminal infection.

The cause of the arteriolar sclerosis underlying the disease is poorly understood. The sclerosis is now usually thought to be due to renal ischemia The disease is common and is said to be commonest among those who lead the strenuous life The tendency to occurrence in certain families has been demonstrated by Hines and others There is a morbid heredity in many of these patients

In families in which both parents have or had hypertension the children in due time have high blood pressure In families in which one parent has or had hypertension one of every four siblings has hypertension All of this is compared with an incidence of 3 or 4 per cent in those whose parents did not have high blood pressure. Draper has emphasized the sthenic type (short, stocky, heavy skeletal frame, broad deep thorax and

marked tendency to obesity) as being particularly susceptible to hypertensive vascular disease

Because of the diffuse nature of the process involving the arterioles throughout both kidneys, some poison carried through the blood must be responsible Such a clinical impression is not supported by the demonstration of the presence of any toxin in the blood of these patients. Other faults of metabolism leading to intoxication, including intoxications depending on internal secretion, especially of the chromaffin tissue, may be important etiologically.

Disease of the afferent glomerular arterioles is usually associated with arterial hypertension Since the voluntary muscles comprise a large part of the weight of the body, Wagener and Keith performed biopsy of muscles and compared the degree of the arteriosclerosis with that observed in the retinas revealed by ophthalmoscopic examinations They found a close agreement in the degree of the arteriosclerosis According to Moritz and Oldt the *presence of arteriolar sclerosis in the small renal vessels is almost* invariably associated with hypertension The absence of renal arteriolar changes betokens an absence of hypertension. When the degree of retinal or renal arteriosclerosis is great, arterial hypertension is invariably present, and renal insufficiency often develops

The structural changes in the renal arterioles, in the arterioles of muscle and in the retinal arterioles consist in a subintimal deposit of hyaline material As this increases in amount, the lumina become narrowed and atrophy of the muscular layer appears The glomeruli become shrunken or fibrosed or converted to hyaline masses, and the corresponding tubules undergo atrophy. Thrombosis of the arterioles, with or without *necrosis of the arteriolar wall, may be present In hypertension with renal insufficiency* Bell described the frequent occurrence of focal glomerulitis, an exudative and proliferative lesion in the glomerular capillaries.

Death from renal insufficiency in hypertensive disease occurs in only 1 of every 10 who have it. When renal failure supervenes in hypertensive disease, it may appear slowly over a period of years Occasionally, however, the onset may be rapid over a period of weeks or months. In these kidneys there are diffuse necrotizing arteriolar lesions characteristic of malignant hypertension and often associated with neuroretinopathy and hematuria

Those who die of renal failure incident to necrotizing arteriolar disease also have similar lesions in the gastrointestinal tract and other internal organs.

SYMPTOMS The onset is insidious, with polyuria and nocturia for a long time. The condition may be first suspected by the finding of albumin in the urine, in association with arterial hypertension at the time of a routine examination

As the disease advances, the symptoms are headache, nosebleed, insomnia, dyspnea, and symptoms of cerebral atherosclerosis such as forgetfulness and unreasonable behavior

If the patient, however, should give a history of transient edemas occurring *in* earlier life, especially in association with one infection or another, the possibility of the condition being an acute exacerbation of a chronic glomerulonephritis is considered A more careful inquiry is made in regard to previous urinary symptoms and transient *edema of the face and the extremities at the time of or following* acute infections of the upper part of the respiratory tract.

In the later stages of arteriolar disease of the kidneys, uremia is common The patients begin to have headaches and visual disturbances often characterized by a *failure of vision due to a retinitis of hypertension* Frequently these patients first consult the ophthalmologist because of a failure of vision resulting from the retinitis The signs of uremia include nausea, vomiting, diarrhea and, toward the end, convulsive seizures, delirium and coma.

An occasional patient who has an approaching renal failure will have a rapid loss of body weight attended by minimal symptoms referable to the kidneys or to the heart On inquiry about the urine, the patient often is aware of having passed an abundant amount of clear urine. In some the symptoms of renal failure will commence with ureteral colic incident to clotted blood obstructing the ureter, as a

result of profuse renal hemorrhage in an occasional patient, particularly men, a clot of blood will obstruct the ureter and cause urinary obstruction.

EXAMINATION. As in essential hypertension, the patient may be of florid complexion, or pale and tense. Often there is excessive sweating but if the renal disease is advanced, the skin is dry.

Evidence of recent loss of weight is common The temporal arteries are often prominent and tortuous in appearance The radial arteries are thickened, tortuous and palpable and seem too long for the arm The pulse rate is increased, often it is from 90 to 100 beats per minute The systolic pressure may be very high, 200 to 250 or more, measured in millimeters of mercury, and 130 diastolic; pressures as high as 300 systolic and 160 diastolic are sometimes met with in this disease. The heart is enlarged The apex beat is displaced downward and to the left. On palpation the cardiac movements are felt as forceful and determined The rate is usually regular. The aortic second sound is increased. Often there is a soft systolic murmur, heard best at the aortic area

Edema is not present unless there is a beginning myocardial insufficiency. When the heart begins to fail, edema may appear, with orthopnea and gallop rhythm; the urine then may become scanty, owing to the superimposition of a renal stasis upon the renal atrophy due to the sclerosis of the arterioles.

There may be only a trace of albumin in the urine, indeed, at times, albumin as measured by clinical means may be absent altogether. There is very little sediment, though on centrifugation a few hyaline casts will usually be found and, occasionally, a granular cast and a few erythrocytes.

In the early stages of the disease, and when there is no cardiac decompensation, the specific gravity of the urine is often less than 1 020, or fixed at about 1 010. The concentration of the blood urea and results of the urea clearance test are normal Concentration of serum sulfates may be increased In the later stages of the disease renal functional activity is greatly reduced as determined by all tests. The greatest concentration of blood urea known (700 to 800 mg. per 100 ml. of blood) occurs terminally in this disease

DIAGNOSIS The hypertension and the ophthalmoscopic findings which differentiate arteriolar sclerosis from glomerulonephritis, and the hypertension and evidence of decreased renal functional activity render the diagnosis obvious.

A constant polyuria, with low specific gravity of the urine, a trace of albumin in the urine with a few hyaline casts, along with chronic arterial hypertension and hypertrophy of the heart, and a concentration of blood urea of more than 60 mg per 100 ml of blood make the diagnosis certain If the patient is seen for the first time only after cardiac decompensation has set in, there may be temporary difficulty in making the diagnosis, for the symptoms of the arteriolar nephropathy are then masked by those of the superimposed chronic passive congestion; moreover, *the attention is then likely to be directed to the congestive heart failure.*

The differentiation of the disease from chronic glomerulonephritis in patients less than 45 years of age may be difficult or impossible during life unless the earlier history of the patient is known The symptoms are practically identical in the two conditions, and, as far as the patient is concerned, it is a matter of indifference as far as length of life is concerned If the physician avoids excessive laboratory procedures, the patient will be grateful to him

Renal Atherosclerosis and Hypertension. In a series of 145 consecutive necropsies Richardson attempted to determine the incidence of lesions which might cause narrowing of the main renal arteries and their relation to essential hypertension Thirty-two of the patients had had essential hypertension and 113 had been free from hypertension In 25 of the 32 there was apparent stenosis of one or both main renal arteries by atherosclerotic plaques In 22 of them the plaques were confined to a short segment of each artery near the aorta, in 2 the plaque

was confined to one renal artery immediately proximal to the bifurcation and i
1 the renal artery showed no narrowing in the main trunk but the inferior branc
of the primary division was definitely stenotic. In 8 the plaques were associate
with a generalized atherosclerosis, in 12 an atheroma was limited to the aort
and in 5 no nodular atheroma was discovered. In the remaining 7 of the 32 there
were no sclerosing lesions of the main renal arteries. In the 8 with unilateral stenosis
which were included in previous numbers for various reasons, microscopic exam
ination of the ischemic and nonischemic kidneys failed to show any difference be-
tween them. In 3 there was malignant hypertension Afferent arteriolar necrosis
occurred with equal frequency in the two kidneys. In 105 of the 113 without a
history of hypertension the main renal arteries exhibited no lesions and in 8
atherosclerotic plaques were present; in 6 they were unilateral The degree of oc-
clusion was comparable to that seen in essential hypertension in only 3 Accessory
renal arteries were present in 6 These data suggest that atheromatous plaques may
be capable of producing renal ischemia and consequent hypertension analogous to
experimental hypertension

Atherosclerosis of the Kidneys. The kidneys in atherosclerosis may be of normal size, slightly enlarged, or reduced in size, and they are firm Scattered over the kidneys are seen depressed spots corresponding to localized or patchy atrophy due to atherosclerotic disease of the vessels supplying the part The difference between the atherosclerotic process and that of the arteriolar nephropathy lies in the fact that the atherosclerotic kidney is affected near the renal vessels of a larger caliber In arteriolar nephropathy the small arterioles throughout both kidneys are involved, leading to an atrophy evenly distributed throughout the kidneys and always associated with similar arteriolar changes in the other organs of the body Usually, unless both atherosclerosis and arteriolar sclerosis are associated, the larger peripheral vessels, such as the radial artery, also are atherosclerotic

The cause of the atherosclerotic nephropathy is that of atherosclerosis in general, about which little is known.

There are usually no symptoms unless renal failure has begun The kidneys may for a long time be able to excrete a normally concentrated urine Errors in diet, exposure to cold, alcoholic excesses, or bad colds may cause the appearance of an increase in the albumin in the urine and the number of casts.

In atherosclerosis examination reveals radial and brachial arteries which are sclerotic, lacking in elasticity and tortuous, they therefore seem too long for the arms The blood pressure reveals a high systolic pressure (180 to 190 mm. of mercury), the diastolic pressure is 80 or at most 90 mm. There may be a rough systolic murmur over the precordium The heart is not enlarged

The urine may contain a trace of albumin, but it is often free from albumin There is generally some polyuria, and the specific gravity may be normal, or decreased and fixed. The sediment contains a few hyaline casts. A few erythrocytes can nearly always be demonstrated in the urine.

The slight polyuria, the cylindruria, the transient albuminuria, the peripheral atherosclerosis (thickened radial), and the signs of atherosclerosis elsewhere in the body often permit of a presumptive diagnosis. Usually the condition is not discovered until necropsy In this form of arteriosclerosis of the kidneys, renal decompensation rarely occurs unless there is cardiac decompensation or severe infections, surgical operation, or a serious accident.

Embolic Nephritis (*Acute Focal Glomerulonephritis*) There are forms of focal glomerulonephritis and of embolic focal nephritis in which there is evidence that only minute disseminated regions in the kidneys are involved, the rest of the renal structure remaining intact. These instances depend apparently on the lodging of the infective emboli, often of low grade, in the kidneys. One of the best known ... the embolic glomerulitis which occurs during the course of bacterial endo-

carditis in which single glomerular capillaries may be thrombosed at the site of embolic lodgment.

In focal nephritis there may be no symptoms referable to the kidneys except the changes in the urine (albuminuria, microscopic hematuria). Uremic symptoms do not develop, since a great deal of healthy renal tissue remains As a rule, edema does not occur, though fugitive edemas are sometimes observed. There is no increase of the blood pressure

When septic emboli reach the kidneys and cause an embolic focal nephritis, miliary abscesses may occur in the kidneys These are met with, for instance, in general staphylococcal septicemia and in bacterial endocarditis

The diagnosis is rarely made during life

Urinary Infections. Infections of the urinary organs in men, women and children are common and often heal spontaneously without producing known illnesses or leaving residua If they do not heal, they do varying degrees of injury to the urinary apparatus and the general health The general health may be regained but injury to the urinary organs may remain, and thus urinary infections tend to recur after remaining symptomless for years A urinary infection contracted by an infant girl, if it does not heal, recurs during childhood, reappears during the early period of womanhood as the pyelitis of defloration, returns during gestation, and thereafter again and again

Urinary infections are so common during infancy and pregnancy that they are designated as pyelitis of infancy and pyelitis of pregnancy They recur when resistance to infection is lowered, as after exposure to inclement weather, after surgical operations, and during any illness, even of brief duration The urinary tract is prone to focalize and harbor specific infections such as gonorrhea, tuberculosis and septicemias due to pyogenic organisms Urinary infections may occur in healthy persons when a virulent organism gains entrance and becomes focalized in the urinary organs

The common bacteria present in urinary infections are the Enterobacteriaceae (the entire group of organisms) They are gram-negative, nonsporulating rods whose natural habitat is the nearby gastrointestinal tract Urinary infections are often caused by the intestinal saprophytes, the escherichiae. The various gram-positive cocci—streptococci, staphylococci and pneumococci, especially the streptococci—are second in number and importance as agents of chronic urinary infections. Various unidentified diphtheroid organisms and degenerated forms are common in chronic infections. The gonococcus rarely invades the kidneys It causes urethritis and cystitis. The tubercle bacillus is not frequent, but when present it is significant.

The relative incidence of these various bacteria in the urine depends on unknown environmental factors which permit of collective and individual susceptibility. Their discovery depends on the astuteness of the bacteriologist in the selection of bacteriologic cultural methods For instance, some forms of streptococci exhibit cultural caprices and thus may be completely obscured by the more luxuriantly growing Escherichia or coliform bacilli

The *portals of entry* of urinary infections are as follows: urethra, extension from adjacent organs, spread through the lymphatics, hematogenous infections, and the ascending infections

The *female urethra* is constantly exposed to infection from vaginal discharges and anal secretions, from trauma of coitus and childbirth, and from irritation of clothing and the protecting pads used during menstruation. From the urethra, as an *ascending infection,* the organisms may invade the bladder and the upper part of the urinary tract The *male urethra* may be the portal of entry after it has been damaged by infections such as gonorrhea and after trauma and from catheterization In both men and women these infections may remain localized or become ascending infections

was confined to one renal artery immediately proximal to the bifurcation and in 1 the renal artery showed no narrowing in the main trunk but the inferior branch of the primary division was definitely stenotic. In 8 the plaques were associated with a generalized atherosclerosis, in 12 an atheroma was limited to the aorta and in 5 no nodular atheroma was discovered. In the remaining 7 of the 32 there were no sclerosing lesions of the main renal arteries. In the 8 with unilateral stenosis, which were included in previous numbers for various reasons, microscopic examination of the ischemic and nonischemic kidneys failed to show any difference between them. In 3 there was malignant hypertension Afferent arteriolar necrosis occurred with equal frequency in the two kidneys In 105 of the 113 without a history of hypertension the main renal arteries exhibited no lesions and in 8, atherosclerotic plaques were present; in 6 they were unilateral The degree of occlusion was comparable to that seen in essential hypertension in only 3. Accessory renal arteries were present in 6 These data suggest that atheromatous plaques may be capable of producing renal ischemia and consequent hypertension analogous to experimental hypertension

Atherosclerosis of the Kidneys. The kidneys in atherosclerosis may be of normal size, slightly enlarged, or reduced in size, and they are firm Scattered over the kidneys are seen depressed spots corresponding to localized or patchy atrophy due to atherosclerotic disease of the vessels supplying the part The difference between the atherosclerotic process and that of the arteriolar nephropathy lies in the fact that the atherosclerotic kidney is affected near the renal vessels of a larger caliber In arteriolar nephropathy the small arterioles throughout both kidneys are involved, leading to an atrophy evenly distributed throughout the kidneys and always associated with similar arteriolar changes in the other organs of the body Usually, unless both atherosclerosis and arteriolar sclerosis are associated, the larger peripheral vessels, such as the radial artery, also are atherosclerotic.

The cause of the atherosclerotic nephropathy is that of atherosclerosis in general, about which little is known

There are usually no symptoms unless renal failure has begun. The kidneys may for a long time be able to excrete a normally concentrated urine Errors in diet, exposure to cold, alcoholic excesses, or bad colds may cause the appearance of an increase in the albumin in the urine and the number of casts

In atherosclerosis examination reveals radial and brachial arteries which are sclerotic, lacking in elasticity and tortuous, they therefore seem too long for the arms. The blood pressure reveals a high systolic pressure (180 to 190 mm. of mercury); the diastolic pressure is 80 or at most 90 mm. There may be a rough systolic murmur over the precordium. The heart is not enlarged.

The urine may contain a trace of albumin, but it is often free from albumin There is generally some polyuria, and the specific gravity may be normal, or decreased and fixed. The sediment contains a few hyaline casts. A few erythrocytes can nearly always be demonstrated in the urine

The slight polyuria, the cylindruria, the transient albuminuria, the peripheral atherosclerosis (thickened radial), and the signs of atherosclerosis elsewhere in the body often permit of a presumptive diagnosis Usually the condition is not discovered until necropsy In this form of arteriosclerosis of the kidneys, renal decompensation rarely occurs unless there is cardiac decompensation or severe infections, surgical operation, or a serious accident.

Embolic Nephritis (*Acute Focal Glomerulonephritis*). There are forms of ... lomerulonephritis and of embolic focal nephritis in which there is evidence

, the rest of the
on the lodging
the best known
bacterial endo-

There are instances, however, of serious renal infections, such as tuberculosis and pyonephrosis, which are not accompanied by any great inconvenience nor at times seemingly by any serious impairment of health.

There is a tendency for the symptoms of urinary infections to recur if the cause of the recurrence lies in mechanical imperfections such as congenital or acquired strictures, other congenital malformations, horseshoe kidney, or hydronephrosis. In others the cause for the symptoms to recur is hidden in residual foci of infection in the urinary tract, such as the periurethral glands Occasionally it has been thought to be due to distant foci in the tonsils, teeth and sinuses

The diagnosis of a urinary infection depends on the astuteness of the physician in the interpretation of the reports of bacteriologic cultural findings of the urine when correlated with the history and the findings on examination of the urinary organs.

Ascending Renal Infections. An ascending renal infection may be defined as an infection originating in the urinary passages distal to the kidneys and progressing upward until the kidneys become involved

Injury to the kidneys from an ascending infection is often difficult to differentiate as such since the kidneys are subjected to injury from various toxins present in the blood and to derangements secondary to circulatory and metabolic diseases.

Pyelitis. Acute or chronic pyelitis occurs in most instances when a pre-existing obstruction is present However, it may arise without pre-existing demonstrable obstruction The infection usually subsides without leaving any residua in the upper part of the urinary tract Even repeated attacks may disappear and leave no cumulative effect However, repeated infections may impair the ureteral musculature, obstruct portions that are normally narrow, impair renal function and advance to hydronephrosis and pyonephrosis.

In acute pyelitis there is an acute inflammation of the mucous membrane of the renal pelvis and calyces In chronic pyelitis, or pyelonephritis, there is a combination of infection and poor drainage, although in some cases there is neither hydronephrosis or evidence of ureteral obstruction Chronic unilateral pyelitis is often the consequence of a stone in the renal pelvis or the ureter.

[illegible]

filled with pus or fluid The filled capsule may be large and palpable or small and impalpable

While pyelitis is essentially the same disease whenever it is present, various forms are described as follows

1 Pyelitis of Infancy and Childhood The generally accepted explanation of the susceptibility of females to pyelitis is that the urethra is constantly exposed to infection by soiled clothes, diapers, washcloths, and occasionally vaginal discharges Pyelitis in boys has some definite predisposing factor, such as a congenital malformation, or genital or general infection or metabolic disease such as hypoparathyroidism

The organisms present in pyelitis in infancy and childhood are coliform, gram-negative bacilli, streptococci and staphylococci

The tendency to recur is a significant feature of this infection in all age groups, but perhaps this tendency is most significant in children Some girls have recurring attacks all through infancy and childhood With puberty the attacks usually cease. However, before the young woman is 25 years old she may have hypertension. Arterial hypertension and urinary infection subject the young woman to excessive risks especially if childbearing is attempted

2 Pyelitis of Pregnancy In pregnant women and in nonpregnant women the normal vesical urine often contains gram-negative coliform bacilli, streptococci

Direct extension from adjacent organs is infrequent, and is not the mode of infection in the common urinary diseases. For example, a diverticulum of the sigmoid may form an abscess and rupture into the bladder, but this sequence of events is rare even in those who have a diverticulosis of the colon.

In *lymphogenous infection* the organisms follow the lymphatic structures along the ureters or blood vessels in their spread.

Hematogenous infections first reach the renal parenchyma. The characteristic hematogenous lesion is focal abscess, which is often bilateral and multiple The commonly blood-borne organisms which reach the kidneys are two, the staphylococcus and the tubercle bacillus

Tonsillitis or sinusitis is effective in lowering the general health and making the patient more susceptible to any intercurrent infection, whether it is in the urinary tract or elsewhere

The opinion has been expressed by Rosenow, Billings and others that a distant *focus of infection* such as the tonsils, teeth, sinuses or ears may originate urinary infection. In some particular types of urinary infection, such as chronic interstitial cystitis, active focal infections as well as other causes for poor health seem to play a definite role as causative factors of production as well as in maintenance of these conditions However, extraurinary chronic focal infections rarely are significant sources of urinary infection

Any part of the urinary tract or the whole system may be infected. Specific infections tend to affect particular organs Tuberculosis always first attacks the kidneys in women, the kidneys or the epididymides in men In septicemia (especially staphylococcal septicemia) the characteristic lesion is focal abscess in the renal parenchyma.

Urinary infection and varying degrees of urinary obstruction usually coexist If urinary infection does precede obstruction, it produces edema and thus hinders urinary drainage and causes stasis Stasis of urine prolongs infection and increases the amount of tissue damage. Spontaneous attempts to heal the inflammatory process by the host may cause scarring and stricture formation in the urethra and ureters The ureteral muscle is replaced by scar tissue, and strictures weaken ureteral peristalsis, resulting in hydro-ureter, hydronephrosis, and eventually, perhaps, pyonephrosis This is particularly true if the emptying power of the bladder is weakened and there is incomplete evacuation of the infected urine.

Urinary infection and stone often coexist The etiologic relationship between the two is not proved Their constant presence together is more detrimental to the urinary tract than the presence of either condition separately A stone acts as a foreign body, making it impossible to eliminate the infection as long as the stone is present

Urinary salts may be deposited on infected surfaces in the bladder or the renal pelvis. Such encrustations hinder or prevent healing of an otherwise simple urinary infection.

Many urinary infections are of insidious onset and follow an insidious course The symptoms consist of frequency, urgency and burning on urination In some the discomfort is situated in the urethra, while in others it seems to be in the bladder. The pain is worse just before and during micturation The passage of urine gives temporary relief. Urinary infections without apparent localization may cause fever, headache, chills, nausea and vomiting They often commence with or follow infections of the upper part of the respiratory tract If the infection is situated in the upper part of the urinary tract the chills may be severe and the fever high The [illegible] the heights attained by almost any other condition [illegible] ial hypertension Anorexia, [illegible] ns of disease of the upper part of the urinary tract.

There are instances, however, of serious renal infections, such as tuberculosis and pyonephrosis, which are not accompanied by any great inconvenience nor at times seemingly by any serious impairment of health.

There is a tendency for the symptoms of urinary infections to recur if the cause of the recurrence lies in mechanical imperfections such as congenital or acquired strictures, other congenital malformations, horseshoe kidney, or hydronephrosis In others the cause for the symptoms to recur is hidden in residual foci of infection in the urinary tract, such as the periurethral glands. Occasionally it has been thought to be due to distant foci in the tonsils, teeth and sinuses

The diagnosis of a urinary infection depends on the astuteness of the physician in the interpretation of the reports of bacteriologic cultural findings of the urine when correlated with the history and the findings on examination of the urinary organs

Ascending Renal Infections. An ascending renal infection may be defined as an infection originating in the urinary passages distal to the kidneys and progressing upward until the kidneys become involved

Injury to the kidneys from an ascending infection is often difficult to differentiate as such since the kidneys are subjected to injury from various toxins present in the blood and to derangements secondary to circulatory and metabolic diseases

Pyelitis. Acute or chronic pyelitis occurs in most instances when a pre-existing obstruction is present. However, it may arise without pre-existing demonstrable obstruction. The infection usually subsides without leaving any residua in the upper part of the urinary tract. Even repeated attacks may disappear and leave no cumulative effect. However, repeated infections may impair the ureteral musculature, obstruct portions that are normally narrow, impair renal function and advance to hydronephrosis and pyonephrosis.

In acute pyelitis there is an acute inflammation of the mucous membrane of the renal pelvis and calyces. In chronic pyelitis, or pyelonephritis, there is a combination of infection and poor drainage, although in some cases there is neither hydronephrosis or evidence of ureteral obstruction Chronic unilateral pyelitis is often the consequence of a stone in the renal pelvis or the ureter

The fully developed pyelitis, pyelonephritis, and infected hydronephrosis terminates in pyonephrosis or contracted kidney In pyonephrosis the kidney and renal pelvis and the renal parenchyma all may be destroyed, leaving the renal capsule filled with pus or fluid. The filled capsule may be large and palpable or small and impalpable.

While pyelitis is essentially the same disease whenever it is present, various forms are described as follows.

1. Pyelitis of Infancy and Childhood The generally accepted explanation of the susceptibility of females to pyelitis is that the urethra is constantly exposed to infection by soiled clothes, diapers, washcloths, and occasionally vaginal discharges Pyelitis in boys has some definite predisposing factor, such as a congenital malformation, or genital or general infection or metabolic disease such as hypoparathyroidism.

The organisms present in pyelitis in infancy and childhood are coliform, gram-negative bacilli, streptococci and staphylococci.

The tendency to recur is a significant feature of this infection in all age groups, but perhaps this tendency is most significant in children. Some girls have recurring attacks all through infancy and childhood With puberty the attacks usually cease. However, before the young woman is 25 years old she may have hypertension Arterial hypertension and urinary infection subject the young woman to excessive risks especially if childbearing is attempted

2 Pyelitis of Pregnancy In pregnant women and in nonpregnant women the normal vesical urine often contains gram-negative coliform bacilli, streptococci

and staphylococci. During the second trimester of pregnancy there are ureteral dilatation and hypertrophy, or perhaps ureteral atony, hydronephrosis, and usually displacement of the ureters which result in varying degrees of urinary stasis. As a consequence of urinary stasis an infection is prone to develop. The sequence of events in the development of this infection is the same in either pregnant or nonpregnant women The bacteria pass from the bladder and originate a ureteritis, or a pyelitis From a pyelitis may develop hydronephrosis, pyelonephritis, pyonephrosis, or renal or perirenal abscesses. If a fresh urinary infection develops during pregnancy, or a chronic one becomes active at this time the lesions may do more injury and may be followed by more permanently harmful sequelae in the urinary organs than would occur in the nonpregnant woman. Women who have had pyelitis in childhood may have a hypertension and a symptomless urinary infection which becomes evident after the advent of pregnancy These women often have a decrease of renal functional activity.

3 Defloration Pyelitis (Honeymoon Pyelitis) The pyelitis of the honeymoon is an acute urinary infection precipitated by the trauma of coitus It is an uncommon form of pyelitis

In former times there was an opinion held by some physicians that defloration pyelitis was of gonorrheal origin This pyelitis is not an instance of infection from a gonorrheal husband The wife's infection is not gonorrheal The wife usually has a chronic nonspecific urethritis or an infected periurethral gland which is traumatized by coitus and thus reinfects the bladder and urethra In many instances she has had pyelitis during childhood.

There is an occasional woman in whom coitus will cause an exacerbation of a chronic cystitis especially after the menopause

Symptoms of Pyelitis In children there are chills, fever, nausea and indigestion, and prostration There may be some discomfort in the side, with frequency and burning on urination. Between attacks most children are free from symptoms Months or years may intervene between attacks.

In women and men an acute pyelitis may or may not be accompanied by frequency, urgency or burning on urination There may be no symptoms other than fever However, generally there are chills, fever, and often pain in the flank passing downward toward the genitalia. During pregnancy pyelitis is the commonest cause of fever

Examination in Pyelitis The general examination is significant for the absence of physical changes Special examinations of the urinary tract also are often negative if no complications are present Between the attacks the patient seems healthy Examination of the urine between attacks may or may not reveal pyuria. Albumin and an occasional erythrocyte may be found

Local tenderness in the region of the infected kidney and the palpation of an enlarged, sensitive kidney, or hydronephrosis are helpful signs if renal complications are present However, these palpatory signs are not constant even if renal complications are present The blood shows the usual reaction to acute infection in an increase in the leukocytes

Chronic pyelitis is a common source of poor health, and the disease may be difficult to detect The urine may remain clear for a day or two after the onset of general symptoms, the temperature attaining 104 to 106 F (40 to 41 C). If the ureter becomes opened and the infected, purulent urine appears, the fever ceases This sequence of events is diagnostically suggestive of ureteral obstruction and pyelitis.

Diagnosis of Pyelitis The diagnosis of pyelitis is made on the basis of the symptoms of a urinary infection, as have been outlined, and the presence of pyuria, positive cultures of urine obtained from catheterized specimens. The disease should be suspected in pregnant women who have fever and in children who have fever,

chills, and pyuria with or without vesical symptoms As a rule, in all cases the acute symptoms last about a week The tendency to recur is great despite treatment.

Pyelonephritis. Pyelonephritis is originated by the infection of pyelitis extending into the renal parenchyma. Pyelonephritis may occur in an acute or a chronic form With acute exacerbations an acute pyelonephritis is manifested clinically by greater toxicity, higher fever, graver constitutional reactions than is observed in pyelitis The urine is heavy with albumin, and occasionally casts and blood may be present in the urine; at times there is renal insufficiency as shown by a decreased renal functional activity. If the infection involves both kidneys, the condition is more serious than if it is unilateral.

Pyelonephritis also occurs frequently in men who have an ascending urinary infection from any cause (commonly, prostatism)

SYMPTOMS. The general symptoms are chill, fever, anorexia, headache and prostration There may be nausea and vomiting There is discomfort or pain beginning in the lumbar region, crossing the flank and extending downward toward or to the external genitalia Burning and frequency of urination are commonly present. Severe dysuria may occur and the urine may contain blood.

Frequently there are no symptoms A functionless kidney may be revealed by means of an intravenous urogram which is made as a part of a general diagnostic survey for some indeterminate pain Often it is discovered that pyrexia of previously unknown origin is caused by a urinary infection Functionless kidneys may be found in a search for the cause of fever

Results of the general examination may be negative Examination of the urine reveals the presence of pus and usually albumin Additional examinations reveal the presence of decreased renal function and evidence of hyperazotemia The diagnosis is based on a finding of a decreased renal functional activity or a functionless kidney in association with the foregoing history and findings.

Pyonephrosis. In pyonephrosis of a single kidney the renal function in the kidney is for practical purposes abolished, the parenchyma of the kidney is liquefied, and the capsule and the renal pelvis are transformed into a cystic mass containing pus Two types of pyonephrosis, excluding those due to tuberculosis, are distinct: the acute and the chronic

Acute pyonephrosis develops suddenly, in the course of a few days. In reality, it is an acute purulent collection in an infected hydronephrosis. Although renal function is completely destroyed by the acute collection of pus, renal tissue remains and may be restored to function if the pus is drained away immediately

Often it is extremely difficult to connect recurrent attacks of pyelitis with those which have gone before It may be impossible even to suspect from the history or the symptoms that pyonephrosis has developed. During remissions the urine often is normal and sterile

On examination search is made for all possible foci of urinary infection, such as chronic urethritis or other chronic infection or renal stone, and for a congenital malformation causing obstruction to ureteral drainage

Chronic pyonephrosis is characterized by destruction of the renal parenchyma and reduction or complete destruction of renal functional activity. The symptoms are often not differentiable from those of chronic pyelitis.

On examination a mass often is not palpable Intravenous urograms reveal that the kidney is functionless, a state which should be confirmed by ureteral catheterization

The specimen from the kidney obtained through the renal catheter consists of pus only, such a kidney excretes little or no phenolsulfonphthalein. Occasionally a pyonephrotic kidney cannot be catheterized, the ureter having been completely occluded by stricture

Pyonephrosis may be present with normal and sterile urine in the bladder if the

ureter is completely occluded. In every case of recurrent pyelitis a complete urographic study is indicated

The diagnosis of pyonephrosis rests on the demonstration of a cystic mass in the place of a kidney by methods of the urologic examination.

Abscess of the Kidney. Abscess or carbuncle of the kidney is due usually to *Staphylococcus aureus*. It is always of metastatic origin, often being associated with boils or carbuncle of the neck or other superficial regions

The lesion consists of a large ulcerative area in the renal cortex. Generally there is also a perinephritic abscess There is present a furuncle or a recent history of furuncles or a carbuncle Then comes a sudden onset of pain in the region of a kidney, fever, and eventually the formation of a mass in the flank.

There is a tender mass in the flank with fever, prostration, and often clear urine, except perhaps for slight albuminuria as a result of the fever. Intravenous urograms and pyelograms may indicate a cortical renal lesion

Tuberculosis of the Urinary Organs. Urinary tuberculosis is almost always a hematogenous infection The common primary foci are the lungs, bronchial lymph nodes, or intestinal tract

In the kidneys a tuberculous hematogenous infection involves the renal parenchyma first, and the excretory ducts (the renal pelvis, ureter, and bladder) secondarily. This order of progression is in contrast to the ascending infections, for they first affect the excretory ducts, the urethra, bladder, ureters, renal pelvis and finally the renal parenchyma.

Renal tuberculosis is largely a disease of young men and women It occurs, however, in children, in adolescents and in the aged. The right side is more frequently involved than the left side.

Primary urinary tuberculosis may occur in the bladder, the tubercle bacilli having gained entrance through the urethra This is far from the rule, however, for tuberculous cystitis rarely occurs without older lesions in the kidneys or in the genitals in either women or men The primary lesion in the lungs, intestines or lymph nodes may not be demonstrated, for it often is very small and cannot be recognized, and may have never given recognizable symptoms

In men the urinary organs may be infected from some contiguous genital or other structure This mode of infection is rare in women

In the beginning, tubercle bacilli reach the kidneys through the blood stream. If large quantities of the bacilli are disseminated throughout the kidneys as well as the rest of the body, the renal disease is but a part of an acute miliary tuberculosis, which is fatal When there are fewer organisms and the resistance of the host is good, the result is localized lesions in the kidneys. If the vital resistance is high, these miliary tubercles in the kidneys may heal promptly Often only one kidney heals completely The unhealed kidney remains active

Once established, the renal lesion progresses The tubercles progress, necrosis sets in, the tissue breaks down, and cavities form with caseation and abscess The abscesses coalesce, forming large cavities filled with tuberculous pus This condition eventually leads to complete destruction of the renal parenchyma, with the transformation of the kidney into a tuberculous abscess This process may require years for completion Often the slow progression of renal tuberculosis is hastened by secondary pyogenic organisms. The symptoms then resemble those of acute pyelonephritis

In all renal tuberculous lesions, in either men or women, the upper and the lower ends of the ureter are commonly and often severely involved. The ureteral infection begins in the mucosa and progressively infiltrates the ureteral wall, which becomes thickened, nodular, and occasionally occluded, thus shutting off the kidney, which may have ceased functioning by the time the ureter has become occluded, producing the so-called autonephrectomy. The lower ends of nodular ureters can be palpated

Tuberculosis of the *bladder in women* is secondary to tuberculosis of a kidney, and in men, to tuberculosis of a kidney or an epididymis The vesical lesion usually begins as a few scattered tubercles around the affected ureteral orifice. In severe infections it

may be difficult to identify the ureteral orifices The infection extends to other parts of the bladder. Tubercles form, caseate, coalesce, and break down, forming large ulcers The bladder becomes contracted.

SYMPTOMS The symptoms of renal tuberculosis are characteristically chronic The average duration of symptoms, when these patients are first examined, has been about three years. The symptoms are vesical distress, pain in the bladder and kidneys, hematuria, low-grade fever, occasionally chills, and loss of weight.

Vesical discomforts are often the first and may be the only symptom of renal tuberculosis. There may be a mild burning sensation, frequency, nocturia and pain All symptoms are intensified by an attempt to empty the bladder Incontinence is common when severe advanced lesions are present The dysuria may be agonizing, particularly if complicated by a pyogenic infection and when there is advanced disease. Once the disease is established, the vesical symptoms are persistent, without remissions.

The renal lesion seems to progress silently, until an abscess ruptures into a renal calyx, producing hematuria and ureteral and vesical infection Often a dull ache in the renal region, due to formation of abscess, is the first noticeable symptom. A fever, with few or no urinary symptoms, may be the initial symptom In other patients microscopic hematuria may be the first symptom In some the symptoms may commence with bleeding which is grossly evident, and this may be the only manifestation of the disease.

In renal tuberculosis years may pass without constitutional reaction or loss of health. Some patients who have bilateral renal tuberculosis or tuberculosis of the remaining kidney live for years in comparative comfort In other patients renal tuberculosis may progress rapidly The fever is high, loss of weight is rapid, and there are nausea, loss of appetite, weakness and anemia

A more rapid course is often observed when there is a secondary renal infection due to the colon bacillus, the streptococcus or other organism In such event the symptoms resemble those of acute or subacute pyelonephritis

EXAMINATION. Routine physical and roentgenologic examination of the lungs will reveal active pulmonary tuberculosis if present.

The presence of *tuberculous foci around the ureteral orifice* is almost infallibly diagnostic if the examination is made by an experienced cystoscopist, especially if supported by other data, such as the finding of tubercle bacilli in the vesical urine and the obtaining of clear and normal urine from the opposite kidney.

A competent urologist may record that the ureteral orifice is buried in tuberculous ulcerations or granulation tissue, it may stand out prominently. The purulent urine may dribble from it continually There may be complete anuria, due to ureteral occlusion, as in autonephrectomy

In tuberculous renal infections the observation of an impairment of function indicates either considerable destruction of renal parenchyma or ureteral obstruction In either instance the disease is advanced In mild infections there is no impairment of function.

When it is impossible for the urologist to catheterize the diseased ureter, either the ureteral orifice cannot be identified in the mass of ulceration or the ureter is impassably strictured In such cases, if the healthy kidney is secreting normal and sterile urine, it is safe to conclude that the opposite kidney is the one which is involved This impression is confirmed by intravenous urograms, and the nature of the infection is established by isolating tubercle bacilli from the vesical urine.

Lesions of the bladder are the commonest cause of symptoms both before and after nephrectomy Tuberculosis of the bladder is almost always secondary to renal tuberculosis

DIAGNOSIS The tuberculous nature of the renal infection is established by recovery of the tubercle bacillus from the catheterized urine by smear, culture, or

guinea pig inoculation. The presence of a urinary infection may be evident because of the presence of symptoms from an active pulmonary tuberculosis, accompanied by pus and blood in the urine.

As a general rule, the presence of an active focus of tuberculosis in the lungs or elsewhere is a distinct contraindication to nephrectomy. The kidney is enlarged and palpable and the ureter is palpable in 1 of each 3 of those who have renal tuberculosis

After nephrectomy it is generally wise to leave the bladder undisturbed for a few weeks because the vesical lesions usually heal spontaneously after the kidney has been removed If vesical symptoms persist, the stump of the ureter is to be examined. Occasionally a pocket of pus is found in this functionless stump which is maintaining the vesical infection; generally, however, there is a deep-seated, exquisitely painful ulceration of the bladder which apparently defies all forms of therapy.

Bilateral Renal Tuberculosis. In a series of 204 cases of bilateral renal tuberculosis Braasch and Sutton found essentially the same clinical features, symptoms, and associated tuberculous lesions as in cases of unilateral infection. The disease is usually more severe, the associated lesions commoner, the vesical symptoms worse, and the prognosis less favorable than in unilateral renal tuberculosis

Bilateral involvement practically always eliminates the advisability of nephrectomy However, in bilateral renal tuberculosis nephrectomy may be advised when one kidney is functionless and transformed into an abscess, or if it is causing severe hematuria or pain

The general futility of nephrectomy in bilateral renal tuberculosis is illustrated by the studies of Emmett and Kibler and by Braasch and Sutton If the remaining kidney is definitely tuberculous, as shown by the presence of pus and tubercle bacilli in the urine obtained from the ureteral catheter, the prognosis is definitely poor, and the outlook depends on the degree of renal involvement Even in those who have only a few pus cells, without demonstrable tubercle bacilli, the prognosis is worse than if the remaining kidney is normal In those who have tubercle bacilli and more than 10 leukocytes per high power field in the urine from the remaining kidney, the mortality rate is 100 per cent within 10 years subsequent to removal of the more severely infected kidney

The results of medical therapy were reviewed by Braasch and Sutton Of a group of 167 patients suffering from bilateral renal tuberculosis, who were not operated on, 72 per cent lived for 3 years or more, 58 per cent, for 5 years or more, 26 per cent, for 10 years or more, and 16 per cent, for 15 years The chief complaint of those who were living after 10 or 15 years was frequency of urination, they were apparently in fairly good health

Renal Syphilis. The pathologist recognizes both syphilitic nephritis and syphilitic renal gumma Wile reported the passage of *Treponema pallidum* through the kidney and its recovery from the urine

The clinical diagnosis of renal gumma is not made during life, except at the time of surgical exploration, when the patient's infection is made evident by the presence of multiple gummatous lesions in a kidney determined by biopsy and histologic examination

Renal Actinomycos [illegible] infec-
tion There may be only o [illegible]
The infection is general [illegible]
[illegible] the lesions about the head and neck [illegible] facto-
[illegible] e

may be accidentally [illegible] The abscess
periods of time and even after a large part of the parenchyma is involved

look like focal suppurative lesions caused by *Staphylococcus aureus* They may be dispersed or grouped, as in the so-called carbuncle.

The early symptoms often are pain, fever and leukocytosis The fever may appear early, may be of an intermittent type, and therefore may resemble that observed in an ordinary urinary infection Hematuria is not constant Symptoms of cystitis often occur.

The diseased kidney is usually palpable Urographic examination reveals deformity of the pelvis which is not characteristic If there has been a surgical trauma to the kidney, there is a definite and peculiar tendency of the incision to break open after healing seemingly has taken place Pus from the incision should reveal actinomyces when examined directly.

Except in generalized actinomycosis the diagnosis is often made after the kidney has been removed surgically or at necropsy Hunt and Mayo have successfully removed actinomycotic kidneys Antibiotics are now used in treatment of many patients who have these infections

Blastomycosis. Blastomycosis of the prostate, urethra, vulva, bladder and kidney has been recorded by Lewis, Carroll and Stryker and others. Often blastomycosis of these regions is associated with lesions of the skin Examination reveals dermal lesions or a chronic ulcer of the leg from which blastomyces are obtained by examination of the exudate from the ulcer or from the urine and by culture.

It may be difficult to prove pathogenesis of these organisms In urinary infections the organisms are abundant and easily found in the urine

Urinary Stones and Their Location. Urolithiasis is most commonly a disease of adult life except in disorders of calcium and cystine metabolism In these metabolic disorders stones may appear in the kidneys or ureters of children and youths.

Etiology It is generally impossible to point out the specific cause in any certain patient who has urinary stones Clinical experience seems to imply that urinary infections and subsequent changes in the physicochemical characteristics of urine, enhanced by obstruction, prolonged recumbency, climate, water, disorders of endocrine glands (parathyroids) and disorders of metabolism affecting cystine, uric acid and calcium may predispose to stone formation Likewise congenital malformations often seem to predispose to stasis of urine and stone formation More recently the formation of renal stone has been attributed to the diet

Much has been said about the etiologic importance of foci of infection in organs such as the teeth, tonsils, sinuses, ears or uterine cervix in the formation of urinary stones affecting and infecting the urinary organs As a result of these injuries stones form in the urinary passages Proof of this hypothesis is not yet available Nevertheless, all infections, remote and local, in those who have urinary calculi or in those who do not have urinary calculi, should be removed to improve poor health or to safeguard good health

Randall has summarized some of the possible effects of infection on formation of stone (1) It disturbs the colloidal balance (2) Infection produces epithelial or bacterial clumps, which may cause crystallization (3) Infection may cause papillitis (4) Bacteria have been found in, and recovered by culture from, the centers of urinary stones. (5) Urea-splitting organisms alkalize the urine and precipitate alkaline salts In addition, infection causes stasis by weakening the ureteral musculature and causing ureteral stricture It also may so damage the kidney that the kidney cannot excrete normal urine In urine which is culturally sterile the factor of urinary infection cannot be ruled out Sterile cultures are occasionally obtained from purulent urine and from subepithelial inflammatory lesions, for example in Randall's subepithelial plaque in the renal calyx.

Urinary obstruction slows the flow of urine, interferes with peristalsis, and prevents the expulsion of small solid particles of organic material which might develop into calculi

Prolonged recumbency is occasionally associated with the formation of renal or vesical calculi, especially if the cause of confinement is some chronic infection and especially a bone disease

Kimbrough, Denslow and Worgan reported the occurrence of urinary calculi in 15 of 800 young recumbent patients, immobilized for long periods for bone injury The incidence of such a small percentage (2 per cent) of calculus formation in such a large number of hospitalized patients with similar injuries under almost identical management makes it evident that there is a lithiasic diathesis due to general derangement of metabolism or local renal factors or both Reduced fluid intake, stasis and focal infections the writers considered to be the chief etiologic factors.

It has long been supposed that urinary stone is common in certain countries or districts, just as goiter is frequent in certain localities. Such a supposition is totally without foundation, for it is difficult to determine the incidence of urinary stones without the modern methods of examination, which have not long been in use

The cystine calculus is an unusual type of urinary calculi According to Joly, cystinuria is due to a congenital inability to metabolize proteins in the usual complete manner. This explains several of the clinical features of cystine lithiasis. it is occasionally familial, may occur in childhood, affects both kidneys, forms multiple calculi and recurs.

Uric acid calculi in gout constitute another example of calculosis in a metabolic disease. In gout the purine metabolism is disturbed, and uric acid is present in abnormally high amounts in the blood and urine, is deposited in various parts of the body and may also be deposited as calculi in the kidneys.

Albright and co-workers were the first to stress the significance and the frequency of the occurrence of renal stones in those who have hyperparathyroidism Hyperparathyroidism is a rare disease and therefore it cannot be, nor is it, a common cause of renal lithiasis. When hyperparathyroidism is the cause of renal stones they often are present *in both kidneys*

The dietary factor in lithiasis has recently attracted a great deal of attention Urinary stones have been produced experimentally in animals by feeding a diet deficient in vitamin A, but in clinical practice this fact has been of no value in the recognition or the treatment of lithiasis.

Prien studied various phenomena and mechanisms of calculogenesis from the standpoint of crystallography Pure calcium oxalate and calcium oxalate plus apatite, a complex calcium phosphate, were the substances most frequently observed in 1,000 human urinary calculi The nuclei of calcium oxalate monohydrate calculi are composed of that substance or of apatite. It is believed that some calculi originate from an attachment to the renal papilla, as described by Randall Not all calcium oxalate monohydrate calculi originate in this manner, those with a central nucleus and symmetric, concentric layers are believed to originate by crystallization from supersaturated urine No evidence is available to support the theory that foreign bodies, such as desquamated epithelium, act as the nucleus for renal calculi

Symptoms. A stone or stones *in the kidney* may cause *very little or no pain* A large stone (staghorn stone) may fill the whole renal pelvis and most of the calyces Often the stone causes nothing more than local irritation Often a large stone of this type is discovered when investigation is made to find the cause for pus and blood found in the urine on routine examination However, at any time there may be dull or sharp pain of any degree of severity which develops as the result of urinary obstruction caused by some complication produced as a result of the stone The discomfort is usually in the lumbar region and often extends down into the iliac fossa, external genitalia or even to the inner surfaces of the thighs

When a stone enters and obstructs the *ureter*, there are spasm, peristalsis and renal or ureteral colic Ureteral calculi often produce severe colicky pain situated along the course of the ureter. This pain may be so severe that moderate doses of opiates will not bring relief Nausea, vomiting and prostration accompany it

the calculus moves along, the movement is accompanied by pain. As the cal- nears the bladder, vesical symptoms become evident. There is frequency or difficulty in voiding Occasionally the descent of the stone from the kidney to the bladder can

almost be followed by the situation of the pain and the beginning of vesical symptoms Very small stones can be passed without causing symptoms. The amount of pain and the probability of passage of a stone depend on the relative size of the ureteral and urethral lumina and the diameter and smoothness of the stone. In a very narrow ureter a stone not more than 2 or 3 mm in diameter may cause severe colicky pain; in a normal elastic ureter such a stone might not cause any symptoms

The dilated, atonic ureter cannot contract vigorously, and hence in such a ureter a calculus may cause only slight pain or no pain at all. The stone may become embedded in the ureteral wall, further lessening the chance of its ever being passed

Experience teaches that ureteral calculi may cause obscure general symptoms over a period of years. These general symptoms may resemble those of an irritable colon In other instances there is flatulence, loss of weight, low-grade fever and occasional sharp discomforts that may simulate appendicitis, gallbladder disease or some pelvic disorder.

Vesical calculi are uncommon in women In men who have urethral obstruction, usually from prostatism, vesical calculi are common These stones, like renal stones, may cause very few symptoms. Symptoms when present are an intractable cystitis and hematuria There may be difficulty in starting the stream of urine, owing to the valvular action of a stone which may partly occlude the internal urethral orifice. In prostatism this may not be differentiated from the difficulty that is normally present During the passage of ureteral or urethral calculi general symptoms such as nausea, vomiting and prostration are prominent

EXAMINATION. The general examination of the abdomen, back and external genitalia is of value because of the characteristically almost uniformly negative findings.

The urologists may desire one or all of the following measures: intravenous urograms, cystoscopic examination and ureteral catheterization Intravenous urograms are rarely conclusive, and often a cystoscopic examination for inspection of the bladder or for the insertion of ureteral catheters is required

Ureteral catheterization may reveal a stone in the ureter which prevents passage of the catheter, or the catheter may pass by the stone With the catheter in place, the pyelogram then shows that the stones are in the renal pelvis However, stones in the renal pelvis do not give colics until they attempt to descend the ureter.

DIAGNOSIS. If trained hands have performed the manipulations indicated and trained eyes have viewed the roentgenograms, the diagnosis, as of a stone in the ureter, is usually definite

The diagnosis of urinary calculus is inferred from the presence of the symptoms of stone, and often there is a history of having passed calculi previously The urine contains blood and often pus

The urologists always consi [illegible]
passing spontaneously or after [illegible]
possibility cannot be formulate [illegible]
stone to pass if the stone is not more than 5 or 6 mm in diameter; fairly often stones of much larger caliber can be passed If the patient habitually passes ureteral stones, the ureter may become dilated and allow large stones (1 cm or more in diameter) to pass A ureter that is pathologically constricted or has a narrow lumen may catch a stone less than 3 mm in diameter Such a stone eventually may completely occlude the ureter.

The *situation* of the stone influences the decision as to whether or not the stone will pass A stone is more accessible to surgical intervention when it is in the abdominal part of the ureter When it is in the juxtavesical part of the ureter, it is difficult to reach surgically but is more accessible to cystoscopic manipulation.

The composition of a stone influences the decision as to whether or not the stone

will pass. If the stone is present in a gouty patient and therefore possibly composed *of uric acid* and *not obstructing the renal pelvis or the ureter*, a trial at dissolution may be made by alkalizing the urine by drugs or by placing the patient on an alkali-ash diet. In those who have cystinuria and no obstruction of the ureter treatment *similar to that employed in the case of uric acid stone* may be employed

If the urologist reports the presence of hydro-ureter or hydronephrosis, if there is anuria from the affected side, and if there is decreasing renal functional activity, the stone irrespective of its *composition should be removed immediately by the* simplest possible means

Small calculi in the renal pelvis or calyces remain in a calyx for months If there is a urinary infection and if the stone is of the borderline size which may not pass, and if it shows no tendency to leave the kidney, pyelotomy may be considered If there are neither symptoms nor infection, the stone should not be disturbed

Vesical stones are diagnosed by the roentgenologist and on endoscopic examination.

The Nephritides. Febrile *Albuminuria.* In the presence of fever, arising from an acute infection, of thermal origin, or developing after exposure to the wet and to cold air, there may be a mild albuminuria Often too there are casts in the urine In severe infections, such as lobar pneumonia, blood casts and albumin in quantity may be present Most of these albuminurias cease to be manifested when the infec*tion is over. In some, if a sufficient amount of renal damage is sustained, the condi*tion does not clear up It remains silent until a future date, at which time its recurrence is then recognized as an acute exacerbation of a chronic glomerulonephritis

Febrile albuminuria *usually is not of important significance It may* be a so-called glomerulitis or it may indicate only a parenchymatous degeneration of the epithelial cells of the tubules It is the condition which has been termed cloudy swelling of the kidneys by the pathologist in those who have died of acute infections In some instances, when there are certain advanced demonstrable degenerative changes in the epithelium of the renal tubules, particularly fatty deposits, it is called lipoid nephrosis. No such diagnoses can be made clinically, but these possible pathologic changes are to be kept in mind to be distinguished from the acute glomerulonephritis that sometimes complicates acute infections Often time and repeated urinalysis are required after an acute infection has subsided before differentiation of these various *conditions arising from fever can be made*

Glomerulonephritis. An advancement of the changes in the kidneys or the processes which constitute a febrile albuminuria constitute a glomerulonephritis This is particularly true if the febrile disease is due to group A streptococcus, for instance scarlet fever or one of the acute respiratory infections

Glomerulonephritis may follow infections such as pneumococcal pneumonia, staphylococcal and streptococcal infections, diphtheria, influenza, smallpox, measles and rheumatic fever A glomerulonephritis initiated by any one of these *infections* conforms well to type once the acute phase or, in some, the nephrotic phase, has been passed and the glomerulonephritis is established

The consensus at present is *that all instances of chronic glomerulonephritis* have originated as acute glomerulonephritis If this is correct, then the cause of both conditions is the same The chronic glomerulonephritis was once acute but has progressed steadily, or through a latent period, into the chronic phase The recorded proportion of instances of re [illegible] chronic varies in different studies of series [illegible] Many individuals have acute [illegible] medical advice is not sought

The association of glomerulonephritis with infection is not a cause-and-effect sequence Bacteriologic inquiry does not reveal an actual invasion of the kidneys

by the infectious organisms If a nephritis is present it may not be detected owing to the febrile albuminuria or acute cloudy swelling of the kidney.

Acute Glomerulonephritis. The term acute nephritis often includes and is synonymous with acute diffuse glomerulonephritis, acute focal glomerulonephritis, and an acute exacerbation of a chronic diffuse glomerulonephritis.

Acute glomerulonephritis is a sequela in most instances of acute infections by the group A streptococcus. The common infections predisposing to acute glomerulonephritis are infections of the upper part of the respiratory tract, tonsillitis and scarlet fever.

It seems likely that a toxemia from a streptococcal infection, without actual localization of the streptococci in the kidney, can cause the disease Microorganisms other than streptococci, or their toxins, may sometimes be responsible (see Chapter 18).

The height of infection occurs when the concentration of toxins is the greatest The acute nephritis develops during or after convalescence from the infection This time relationship suggested to Leichtenstern the possibility that glomerulonephritis is induced by an immune reaction resulting from infection, and this is as good a postulation as many of those which have been proposed

PATHOLOGY Owing to the presence of certain pathologic findings in the kidneys, many forms of acute nephritis have been described The nephritides which have been attributed to infections have been designated as bacterial, catarrhal, clostridial, croupous, desquamative, diffuse, exudative, focal, pneumococcal, suppurative (staphylococcal), acute suppurative (tuberculous), chronic syphilitic, and trench

The nephritides which are thought to have originated from a toxic substance, probably due to some sort of chronic anaphylactic reaction, include the acute, subacute, latent and chronic forms of glomerulonephritis.

The nephritides due to toxic chemicals are extensive but only the saturnine nephritides, due to lead poisoning, and those due to mercury have received special names The rest are simply designated according to the chemical agent, for instance, tartrate nephritis

The nephritides arising from causes definitely extrinsic to the kidneys and involving the kidneys secondarily have been designated according to the prevailing condition, for instance, azotemic, chloro-azotemic, dropsical, gravidarum, and transfusion nephritis.

There are the nephritides of a chronic nature, progressive and of a more ill-defined etiology than the acute nephritides, which have been designated chronic interstitial nephritis This form of nephritis formerly was thought to be due to any one or to all of several etiologic agents, namely, lead, alcohol and gout, or to be due to an acute nephritis which produced interstitial changes resulting in a decrease of size, the formation of cysts, and an adherent capsule In chronic interstitial nephritis the interstitial tissue increases, and a thickening of vessel walls and the malpighian corpuscles ensues Other names for this form of nephritis are chronic diffuse nephritis, arteriosclerotic kidney, senile kidney, small granular kidney, and small red kidney The term parenchymatous nephritis in contrast to chronic diffuse nephritis, indicates the main changes to be in the renal parenchyma This is the large white kidney of former times.

The foregoing terms are given in order to demonstrate that pathologists have been able to describe the degree and the kind of nephritis in a kidney very much more precisely than the clinician can relate to the pathologic findings the symptoms and the disease which proved fatal to the patient

In the acute nephritides, the common form which follows scarlet fever, the first changes are more interstitial than glomerular. The mildest form of acute glomerular nephritis is manifested by a swelling of the endothelial cells lining the glomerular tufts This stage is soon followed by avascularization of the glomerulus, with an infiltration of erythrocytes into the capsular spaces, necrosis, degeneration and exudation of granular [illegible] to albumin, which then accumulates [illegible] are polymorphonuclear neutrophilic [illegible] more prominent, and finally epithelial crescents are present in the glomerulus

Acute nephritis is commoner in young persons than in middle-aged and older

persons. Males are more often affected than females Pain is *not a feature of this* disease.

SYMPTOMS. Often within a month after an acute infection of the upper part of the respiratory tract, tonsillitis or scarlet fever, there appears edema, first of the face and about the eyes and the eyelids. The edema develops rapidly and is soon observed in the legs Sometimes the edema may be absent or fugitive or it may progress to a general anasarca and on occasion to pulmonary edema

Other symptoms that may be present include fever (*temperature, 100 to 102 F,* 37.7 to 38 8 C) and uremic symptoms. The uremic symptoms, consisting of headaches, dimness of vision, nausea, vomiting and insomnia alternating with mental dullness, vary greatly in severity, sometimes being so mild as not to attract attention. In other instances death from uremic poisoning ensues

A type of the acute glomerulonephritis of insidious onset sometimes complicates lobar pneumonia The onset may be so gradual as not to be noticed unless daily routine *examinations of the urine are made. There may be no edema in the* milder forms The symptoms of the nephritis are so trivial that they are lost sight of in the presence of the prominent symptoms of the primary disease.

EXAMINATION Edema is present, manifested first by puffy eyelids, pasty face and watery eyes Edema next appears in the lumbar region, and later in the legs. In a few cases edema appears before albuminuria or casts are found in the urine. The course of the disease and of the edema is variable

If uremia is present, there is urinous odor to the breath, and there are headache, drowsiness, and, sometimes, convulsions and coma The blood pressure is increased, the systolic pressure being higher than 150 mm of mercury, in about half of those who are examined Tachycardia or occasionally bradycardia, and dryness of the skin with pruritus are observed. A severe anemia is often of serious prognostic import Examination of the urine reveals oliguria, pollakiuria, hematuria, high specific gravity, albuminuria and cylindruria.

In estimating the damage that has been done to the kidney and the relative injury to the glomeruli in some instances and to the tubules in others, the methods of testing functional renal activity should be resorted to as they apply to the water intake and water output and the specific gravity of the urine. These functional tests are the concentrations of the blood urea, serum sulfates, creatinine, and the various clearance tests such as the urea, sulfate, creatinine and the clearances of certain sugars such as inulin Single determinations of the functional tests are of slight diagnostic and prognostic value It is the trend of repeated tests which is significant

DIAGNOSIS. In the acute nephritis of abrupt onset, for instance after scarlet fever, when there are rapidly developing edema, pallor, nausea, vomiting, increased blood pressure, hematuria and albuminuria, there can be no doubt as to the diagnosis It is in the forms of insidious onset that the possibility of the disease is to be remembered and recognized as such as quickly as possible The characteristic features of acute glomerulonephritis are edema of the face, anemia, hematuria, urinary casts and albuminuria In some the urea clearance is decreased and the serum sulfates are increased before hyperazotemia prevails

If the condition of the patient before the onset of the nephritis has been known, and especially if a record of the state of the urine previously is available, the changes in the character of the urine often will indicate the nature of the trouble.

In the differential diagnosis of acute nephritis it is necessary to distinguish it from (1) simple febrile albuminuria, (2) orthostatic albuminuria, (3) chronic passive renal congestion, (4) subacute or chronic glomerulonephritis, (5) amyloid kidney, (6) renal infarct, (7) *the different forms of pyelitis* and pyelonephritis, (8) renal tuberculosis, and often (9) from arteriolar renal disease

Latent Glomerulonephritis. About one half of those who have acute glomerulonephritis recover from the disease, and at the end of about 6 months no evidence

of the disease can be found There are an indefinite number in whom the disease seems to persist in a latent form For instance, there is a continuous excretion of abnormal amounts of albumin and numbers of erythrocytes, but renal function is preserved This period may last for months or even years Some patients may cease to excrete appreciable numbers of erythrocytes but continue to lose sufficient albumin in the urine to deplete the plasma proteins Finally, in some the nephrotic syndrome develops which is characterized by edema, massive albuminuria, low plasma proteins, elevated blood cholesterol, normal blood pressure, and normal or nearly normal renal function as measured by clearance tests In others there is a definite chronic glomerulonephritis on the first examination In still others it seems reasonable that recovery may occur after months of latency, but no proof of such recovery is possible

Subacute or Subchronic Glomerulonephritis There are no diagnostic criteria to separate subacute glomerulonephritis from latent or from chronic glomerulonephritis. There are no objections to these terms, if it is desired to use them.

Chronic Glomerulonephritis Chronic glomerulonephritis is a diffuse destructive process in the kidney causing deforming changes in the glomeruli, in the parenchyma and, to a less extent, in the interstitial tissue of the kidney The urinary abnormalities vary In some the changes are insignificant, while in others the urinary changes are almost diagnostic The urinary changes, edema, secondary anemia, and, usually, a fatal termination in one or two years are characteristic of an unmistakable clinical syndrome.

The cause is the same as that of acute glomerulonephritis

PATHOLOGY The kidneys in chronic glomerulonephritis are characteristically reduced in size, although this is not always the case, even at death the kidneys may be of almost normal size. The gross renal weight does not parallel the number of remaining functional nephrons Some nephrons are atrophic, while others are definitely hypertrophic, the hypertrophy affecting particularly the proximal convoluted tubule There is an increase in the number of vasa recta, that is, arterioles whose capillaries are distributed to tubules without the interposition of a glomerulus Some tubules whose glomeruli have been destroyed persist as aglomerular tubules The tubules have great power for regeneration and recovery wheras glomerular healing is difficult and uncertain

The early detectable change in the glomerulus is a hyaline change in the glomerular membrane After this is seen a proliferation of the endothelial cells of the capillaries or of the epithelial cells about the glomerular tufts The glomerular capillaries become obstructed and epithelial crescents form in the capsule The presence of hemorrhages and coagulated albumin varies with the acuteness of the process.

By the time death comes, there are widespread vascular disease, and enlargement of the heart Often death is due to congestive heart failure.

SYMPTOMS There may be only the symptoms of weakness and anemia accompanied by edema The edema may be slight at first, and just a little puffiness of the eyelids in the morning or of the ankles at night is all the patient has observed. Gradually, however, the edema increases The most extreme examples of anasarca are those due to glomerulonephritis The subcutaneous tissues all over the body are involved The dropsical fluids fill the serous cavities of the body. There are general weakness, and loss of appetite

Uremic intoxication of greater or less degree is nearly always present, though the symptom of edema is more obvious than are the symptoms of uremia The manifested uremic phenomena consist of headache, drowsiness and digestive disturbances. It is only occasionally that the severe uremic manifestations are present, such as convulsions, coma, uremic amaurosis, and mental disorders or psychosis

Other patients first come under observation with symptoms of an acute nephritis. They give a history of a recent tonsillitis or other infection On examination the urinary findings represent an acute nephritis, and only the presence of the combina-

tion of cardiac hypertrophy, anemia, retinopathy and low renal function indicates the existence of chronic disease.

In still other patients the symptoms of the acute stage evolve rapidly into a chronic stage. The edema subsides, but the albuminuria, hematuria, hypertension and diminishing renal function adversely progress. However, in the majority, a history is obtained that the symptoms of the initial stage subsided, the blood pressure returned to normal, and erythrocytes disappeared from the urine, although massive albuminuria persisted and the edema became pronounced. This so-called nephrotic *phase of glomerulonephritis may persist for months or years. Eventually the albuminuria* decreases and edema disappears, but hypertension becomes manifest and there is a progressive decrease in renal function These patients, however, may pass through or into a *latent stage* (latent glomerulonephritis) in which persistent albuminuria is the only recognized abnormality. Other patients continue to show slight or moderate elevation of blood pressure after an acute attack, with only a slight albuminuria For a long time, even many years, the clinical course in these patients closely resembles that of primary or essential hypertension.

Examination The blood pressure is not elevated to the degrees seen in arteriolar sclerosis and does not show the fluctuations which are characteristic of the early stages of this disease While systolic pressures of 250 mm. of mercury and diastolic pressures of 150 or more do occur in chronic nephritis, the more usual range is 160 to 180 systolic and 100 to 120 diastolic. As a result of the hypertension there is hypertrophy of the left ventricle, although there may be no dilatation or detectable cardiac enlargement Retinal lesions, with hemorrhage, exudate and papilledema occur The anemia tends to parallel the degree of impaired renal function. It is usually normoblastic in type, and counts of 2,000,000 erythrocytes in each cubic millimeter of blood and a concentration of hemoglobin of 40 per cent are common findings

The urine in chronic glomerulonephritis is usually increased in volume, amounting to 2 to 3 liters a day. The specific gravity is low, and the patient cannot excrete a concentrated urine during a concentration test In severe impairment the specific gravity becomes fixed within a point or two of 1 010, the patient being unable to excrete either a more dilute or more concentrated urine

There is usually a persistent albuminuria which, however, may be slight In contrast to the urine in arteriolar nephrosclerosis, there is a constant excess in the number of erythrocytes in the sediment The excess, however, may be *slight, and* only detectable by an Addis count Casts likewise are present, but may be scarce, particularly in dilute urine The number of erythrocytes increases during periods of activity or rapid progress of the disease

During the progress of the disease there are phases characterized by albuminuria, large number of casts, manifest edema, only slight hematuria, and no or only slight cardiovascular changes In about half of these cases arterial hypertension does not develop In rare instances there may be blood pressures in the lower limits of the normal range In the same cases, as the disease develops, the edema may disappear, albuminuria may decrease, hematuria increase, polyuria become marked, and there may be extensive cardiovascular changes and arterial hypertension

Whenever possible, tests of renal function should be undertaken, since they may reveal the state of renal compensation or decompensation, the relative degree of injury to the glomeruli, or of the tubules, and the progress of the disease *Of these* tests, those that measure the variations of the specific gravity of the urine, the urea clearance test and other clearance tests are the most desirable It is the general trend of the test that is the most valuable in determining the progress of the disease

Diagnosis The presence of albuminuria, hematuria, cylindruria, and oliguria, ... with edema, in a young patient who does not have cardiac decompensation,

makes the diagnosis of glomerulonephritis most likely. In the older patient (40 to 50 years of age) the distinctions to be made are often between (1) subacute diffuse glomerulonephritis and (2) acute diffuse glomerulonephritis, or (3) when an acute renal failure occurs as a part of an advancing chronic arteriolar sclerosis with hypertension The history, and the physician's knowledge of the previous condition of the patient and his urine, may well be diagnostically decisive In the absence of such knowledge there may be real difficulty for a time in arriving at a satisfactory differentiation between glomerulonephritis and arteriolar disease Hematuria is more constantly present in glomerulonephritis than in arteriolar disease

Wagener and Keith have expressed the belief that the differential diagnosis between chronic glomerulonephritis and arteriolar sclerosis with hypertension and renal failure can be made from the retinal changes present (see Hypertension, Chapter 10).

The Nephrotic Syndrome (Lipemic Nephrosis) The syndrome presents certain uniform and consistent features, such as gross edema, hypoproteinemia, hypercholesteremia, lipemia and heavy proteinuria in the absence of congestive heart failure. It is convenient from a clinical point of view to regard the syndrome as an independent entity Heymann and Alperin prefer the term "lipemic nephrosis with or without nephritis " This term keeps the nephrotic diseases in one group, separates them from chronic glomerulonephritis and does not imply the priority of the nephritic component It also alters the hopeless prognosis for chronic glomerulonephritis which has been observed in nephrosis with nephritis The nephrotic diseases have a different age distribution from that of acute hemorrhagic glomerulonephritis. The maximal disposition for the nephroses is found in the second year of life while glomerulonephritis is still rare The incidence of glomerulonephritis increases with age up to puberty, whereas the incidence for the nephrotic diseases decreases.

The etiology of the nephrotic syndrome is not known The syndrome is by some believed to be renal in origin, either a disease entity or a phase in chronic glomerulonephritis, while others believe it to be of extrarenal origin, caused by some disturbance of the protein metabolism

Lange and his associates believe the nephrotic state to be a generalized disease of the small blood vessels with a tremendous increase in capillary permeability The formation of edema, in their opinion, is due to this fact and not primarily to the lowered colloid osmotic pressure Preceding infections, which are observed in patients who have acute glomerulonephritis, are not regularly observed in children ill with nephrosis with or without nephritis

Janeway and his associates and Blumberg and Cassady noted a pronounced diuresis in children with chronic glomerulonephritis who contracted measles Seegal and Wertheim have stated, however, that in some patients the occurrence of an infectious disease in the course of the nephrotic syndrome may prove detrimental, inducing hematuria and further accumulation of edema. Patients with the nephrotic syndrome are lacking in resistance and usually die of an intercurrent infection It is also held that a specific fault in the renal excretion of sodium is the important factor. The alleviation of the nephrotic syndrome during various infectious diseases has frequently been observed Some believe that renal dysfunction in the disposal of water and electrolytes is chiefly concerned

Symptoms The onset is usually insidious, the patient feels weak and tires easily The fatigue may have begun weeks or months prior to onset of the edema, but the patient usually does not consult a physician until the edema becomes obvious. To the patient, the edema is the disease

In other patients there may be a history of sore throat or acute respiratory infection from which there was prompt and apparently satisfactory recovery Often the rapid onset of edema is preceded by a feeling of heaviness and stiffness in the extremities The edema soon becomes diffuse. The body cavities fill with fluid Shortness of breath follows. Usually there is no fever. The appetite is poor or absent.

EXAMINATION. The results of physical examination are negative except for the massive edema On examination soon after the appearance of the edema it is dependent, then generalized, and often associated with ascites and hydrothorax The edematous tissue is peculiarly soft, pitting easily on pressure. The amount of edema varies inexplicably at times, and cannot be correlated with changes in the concentration of plasma proteins or the amount of protein excreted in the urine.

The findings of hypercholesteremia and hyperlipemia on examination of the blood in the nephrotic syndrome are perplexing, for the fat content of the diet appears to have little influence on the plasma composition The subclinical forms of the nephrotic syndrome may be detected by the determination of the values for serum albumin and serum cholesterol An abnormally low concentration of serum albumin in association with hypercholesteremia may be evidence of the presence of the nephrotic syndrome.

The plasma protein composition is greatly altered in the nephrotic syndrome There is a significant reduction in albumin, while the globulin content may rise, especially in amyloidosis, may remain unchanged or may fall The urinary proteins are probably derived from plasma by a filtration mechanism The obvious site of this filtration is the glomerulus, indicating a defective glomerular activity, even though the glomeruli show little or no gross alteration. The urine is highly concentrated and contains cellular elements of casts of various kinds with little or no blood. Improvement in the patient's condition is accompanied by a decrease in urinary protein and an increase in plasma proteins

DIAGNOSIS. The diagnosis of the nephrotic syndrome is based on the presence of massive albuminuria, edema, and reduced concentration of protein in the plasma, with reversal of the albumin-to-globulin ratio, usually accompanied by an increase in plasma lipoids and a low basal metabolic rate If the disease long persists, hematuria or hypertension or nitrogen retention or all three tend to be present During the course of a chronic infection findings comparable to those of nephrosis may be indicative of amyloidosis

Lower Nephron Nephrosis. The term lower nephron nephrosis includes renal disease characterized by tubular degeneration and necrosis with subsequent regeneration, deposits of pigment in the tubules, and interstitial inflammation but no visible glomerular alterations The disease may be caused by a wide variety of agents which induce prolonged shock, renal ischemia and anoxia or allergic and toxic damage to the tubules Some of the best known causes are (1) extensive burns or wound shock, especially the crush syndrome, (2) hemoglobinuric nephrosis due to mismatched blood, (3) sulfonamides, (4) inhalation of carbon tetrachloride, (5) blackwater fever and other factors responsible for intravascular hemolysis of erythrocytes, (6) hyperthermia and various poisons and on rare occasion after transurethral resection of the prostate gland

The important features are the acute development of oliguria or anuria and hypertension, and the invariable danger and frequent occurrence of congestive heart failure.

The development of heart failure usually is precipitated by the parenteral administration of fluids in an effort to alleviate vomiting, promote diuresis or maintain fluid or electrolyte balance Intracellular breakdown may be caused by excessive administration of intravenous fluids; when present, such breakdown contributes to the excess of extracellular volume and edema Both of these factors are important because there is no urinary output or only an insignificant one Cardiac dilatation, gallop rhythm, pulmonary congestion and hydrothorax, subcutaneous edema and ascites are common Death is not common, but when it does occur it is often due to acute pulmonary edema as a part of the left ventricular failure

When the concentration of blood urea begins to decrease and diuresis is present, caution is exercised in pursuing any immediate urge in the restoration of acid-base

and electrolyte balance These measures are best undertaken slowly and preferably by oral administration of these substances. In most instances no therapeutic measures are necessary when the basic renal lesion is healed, renal function is restored and a normal diet is permitted. As a rule, lower nephron nephrosis is a spontaneously reversible condition in which diuresis begins 2 weeks after onset, independent of treatment

Amyloid Kidney. Amyloidosis of the kidney is a degeneration of the kidney in which amyloid is deposited in the organ, chiefly in the walls of the blood vessels, sometimes in the membrane of the renal tubules Amyloid disease is often a generalized process with similar deposits occurring in the liver, spleen, heart, intestine, skin and lungs as well as in the kidney

Amyloid deposit occurs in cachectic states due to chronic pyogenic infections, syphilis, or tuberculosis, and as a primary disease beginning insidiously. The diag- [illegible] in several organs. [illegible] one to occur may be [illegible] suppurative pyelitis, and bronchiectasis; furthermore, in chronic tuberculosis of the lungs, bones and joints, amyloid is common, and in tertiary syphilis it is frequently seen. In some instances suppuration does not precede the onset of symptoms of the disease. These are examples of primary amyloidosis (see Chapter 22)

When amyloid degeneration occurs in the kidney, the organ enlarges and the cortex broadens and grows waxy in appearance On section, the glomeruli stand out distinctly. If a little Lugol's solution is poured over the surface, the glomeruli and the walls of blood vessels and of tubules that contain the amyloid material stain a dark mahogany brown color

There are no symptoms characteristic of amyloid disease of the kidney. If, during the course of an illness which has been diagnosed as nephrosis, there is a sudden development of renal failure, and death occurs, the patient usually has had amyloid disease of the kidney Also it is to be remembered that amyloid disease can be implanted in a kidney that is already the seat of other forms of renal disease aside from nephrosis, such as arteriolar renal disease.

Usually albuminuria, cylindruria, edema and enlargement of the spleen and liver are present. Often there may be chronic suppuration, tuberculosis or syphilis Mild forms of the disease, however, and even many of the severer forms are not recognized until necropsy.

The diagnosis of amyloid kidney can be made if there is an abundant amount of urine, of low specific gravity, yet heavy with albumin These findings are present in the absence of cardiac and vascular phenomena of an arteriolar sclerotic kidney. When the foregoing findings are associated with an enlarged liver and spleen, or at least one of them, especially the spleen, and when at the same time there is present a chronic suppurative process, the diagnosis is made Amyloid disease is suspected if, in a patient who has chronic nephrosis, uremia suddenly develops and death ensues There are those who have chronic primary amyloidosis without any of the foregoing findings present The reaction to the Congo red test is positive in about 6 of every 10 of those who have amyloidosis This test rarely gives a false positive reaction

Renal Trauma. Renal injuries often are sustained from trauma to the lumbar region The trauma is followed by pain in the region of the kidney or the abdomen, shock, nausea, vomiting, and the passage of bloody urine. The degree of shock as well as all other manifestations vary with the seriousness of the injury

The general examination may reveal a pallid face, cold extremities, unconsciousness, rapid and thready pulse, low blood pressure, and other signs of serious injury

Local findings are tenderness, resistance, and muscle spasm over the side of the

EXAMINATION. The results of physical examination are negative except for the massive edema On examination soon after the appearance of the edema it is dependent, then generalized, and often associated with ascites and hydrothorax. The edematous tissue is peculiarly soft, pitting easily on pressure. The amount of edema varies inexplicably at times, and cannot be correlated with changes in the concentration of plasma proteins or the amount of protein excreted in the urine.

The findings of hypercholesteremia and hyperlipemia on examination of the blood in the nephrotic syndrome are perplexing, for the fat content of the diet appears to have little influence on the plasma composition. The subclinical forms of the nephrotic syndrome may be detected by the determination of the values for serum albumin and serum cholesterol An abnormally low concentration of serum albumin in association with hypercholesteremia may be evidence of the presence of the nephrotic syndrome

The plasma protein composition is greatly altered in the nephrotic syndrome. There is a significant reduction in albumin, while the globulin content may rise, especially in amyloidosis, may remain unchanged or may fall. The urinary proteins are probably derived from plasma by a filtration mechanism The obvious site of this filtration is the glomerulus, indicating a defective glomerular activity, even though the glomeruli show little or no gross alteration The urine is highly concentrated and contains cellular elements of casts of various kinds with little or no blood Improvement in the patient's condition is accompanied by a decrease in urinary protein and an increase in plasma proteins

DIAGNOSIS The diagnosis of the nephrotic syndrome is based on the presence of massive albuminuria, edema, and reduced concentration of protein in the plasma, with reversal of the albumin-to-globulin ratio, usually accompanied by an increase in plasma lipoids and a low basal metabolic rate If the disease long persists, hematuria or hypertension or nitrogen retention or all three tend to be present. During the course of a chronic infection findings comparable to those of nephrosis may be indicative of amyloidosis

Lower Nephron Nephrosis. The term lower nephron nephrosis includes renal disease characterized by tubular degeneration and necrosis with subsequent regeneration, deposits of pigment in the tubules, and interstitial inflammation but no visible glomerular alterations The disease may be caused by a wide variety of agents which induce prolonged shock, renal ischemia and anoxia or allergic and toxic damage to the tubules Some of the best known causes are (1) extensive burns or wound shock, especially the crush syndrome, (2) hemoglobinuric nephrosis due to mismatched blood, (3) sulfonamides, (4) inhalation of carbon tetrachloride, (5) blackwater fever and other factors responsible for intravascular hemolysis of erythrocytes, (6) hyperthermia and various poisons and on rare occasion after transurethral resection of the prostate gland

The important features are the acute development of oliguria or anuria and hypertension, and the invariable danger and frequent occurrence of congestive heart failure

The development of heart failure usually is precipitated by the parenteral administration of fluids in an effort to alleviate vomiting, promote diuresis or maintain fluid or electrolyte balance Intracellular breakdown may be caused by excessive administration of intravenous fluids, when present, such breakdown contributes to the excess of extracellular volume and edema Both of these factors are important because there is no urinary output or only an insignificant one Cardiac dilatation, gallop rhythm, pulmonary congestion and hydrothorax, subcutaneous edema and ascites are common Death is not common, but when it does occur it is often due to acute pulmonary edema as a part of the left ventricular failure.

When the concentration of blood urea begins to decrease and diuresis is present, caution is exercised in pursuing any immediate urge in the restoration of acid-base

they so numerous or of such character as to be confused with polycystic kidney Solitary cysts are usually unilateral. Small cysts are found in arteriosclerotic kidneys, and simple cysts may be present in kidneys that otherwise are normal These cysts result from localized obstruction, and occasionally may become very large. Hydatid and dermoid cysts are rare

Multiple cysts are occasionally confined to one part of a kidney They are compactly grouped, and the remaining tissue is normal This condition may have its origin in tubular obstruction, or it may be of congenital nature, the same as bilateral polycystic kidneys

On more detailed study, numerous areas of localized infiltration, with hyalinization of glomeruli, are present There is usually marked thickening of the smaller arteries and arteriolar walls identical in appearance with that observed in hypertensive disease This finding is a very important factor in the progress of the disease, and is associated with hypertension, which is usually present or develops as the disease progresses.

SYMPTOMS. The onset of symptoms may be very gradual, with weakness, periods of malaise, headache, nausea and vomiting In some patients renal insufficiency is manifested by rapid failure, and uremia may occur within a relatively short period of time Cerebral hemorrhage may occur in those who have hypertension which has caused no distressing symptoms prior to the stroke Complications from intercurrent disease may appear as the result of debility and anemia In some cases the only symptoms may be those caused by hypertension Congestive heart failure often occurs late

Many patients are unaware of the gradual, progressive enlargement of the kidneys which may have extended over many years prior to the onset of the first symptoms

Pain referred to the lumbar region, or to an upper, lateral abdominal region, is a common symptom The pain is usually unilateral, and is described as a dull ache, although it may become severe Occasionally one or more cysts may become of enormous size and be the cause of considerable discomfort Mechanical pressure on surrounding organs by these cysts may also be a factor in the production of pain Some patients obtain relief by lying down, others by supporting the kidneys with abdominal pads Sudden hemorrhage into a large cyst may be the cause of severe, acute pain The passage of blood clots, with ureteral obstruction, causes acute renal pain The pain may be accompanied by fever and other evidence of acute renal infection, or by ascending pyelonephritis caused by temporary urinary obstruction

Gross hematuria is present in a third of the cases It occurs at irregular intervals and frequently is brought on by violent exercise or jarring As a rule the hemorrhage is profuse and often accompanied with a clot, which may cause renal colic. The hematuria is similar to that occurring with renal neoplasm, and if but one kidney is enlarged, the two conditions may be easily confused. Microscopic evidence of blood was reported by Braasch and Schacht to have been found in the urine of 85 patients Dysuria or frequency of micturition was noted by only 15 per cent of patients

EXAMINATION On physical examination bilateral palpable tumors are present in more than one half of the patients and unilateral enlargement is present in a few Some will have no palpable enlargement of the kidneys. Although both kidneys are usually markedly increased in size, there is often a decided difference in size It is not unusual to find one kidney but little larger than normal and the other several times as large as normal Heavy muscular abdominal walls or fat may interfere with clinical recognition of renal enlargement of moderate degree. It is surprising how large a kidney may be and still escape detection on palpation As the kidneys become enlarged they frequently change their position Occasionally la[illegible]cement of one or both kidneys oc[illegible]

abdomen containing the injured kidney. A *mass may form.* The urine contains blood. There may be leukocytosis. Often there is no fever until the extravasated blood and urine begin to be absorbed or until infection becomes established

The most valuable special diagnostic means are the ordinary roentgenogram, the intravenous urogram, and occasionally, if manifestations are not severe, cystoscopic examination

Intravenous urographic examination is invaluable. It can be used successfully in patients who are unconscious and unable to tell anything about the injury and in whom it is impossible to elicit tenderness, pain, or muscle spasm The procedure not only reveals the functional capacity of the *injured kidney but also demonstrates the diffusion* of the fluid into the perirenal tissues, and also reveals the presence and function of the opposite kidney.

Renal Tumors. Renal tumors are commoner in men and children than in women *In children renal tumors are the commonest neoplasms of the upper part of the* abdomen. In adults the incidence is higher from 40 to 60 years of age than in other periods of life

Benign Renal Tumors. Adenomas, fibromas and fibrolipomas are rare. Angioma *is found still more rarely.*

The common benign renal tumor is the renal cyst There may be a single cyst, or multiple cysts that involve the entire kidney When many cysts of the kidney are present, the condition is termed polycystic disease of the kidney. The origin of these cysts is not known. They are usually small, though such a cyst may contain several liters of fluid which resembles urine Renal cysts cannot be diagnosed clinically.

A simple cyst which contains blood is known as a hemorrhagic cyst. The origin is unknown

Perirenal cysts arise from embryonic rests in the lumbar regions

Polycystic Disease. The hereditary tendency of polycystic kidney has been observed There are instances in which several members of a family, of several generations, have been afflicted with polycystic disease In 1 of Schacht's cases the condition was apparently present in representatives of four generations, in 2 cases, in three generations, and in 5 cases, in two generations. There apparently is variability in the frequency of inheritance in different families

The disease is rarely manifested before puberty The average age at which the disease becomes manifest is from 30 to 40 years, occasionally from 40 to 50 years However, some patients have no subjective evidence of disease until 50 to 70 years of age Polycystic disease affects both sexes The incidence of *congenital* polycystic kidney found at necropsy is three times as great as that diagnosed clinically (Schacht).

The cysts increase in size and multiply and the pelvis is encroached on and becomes deformed The calyces may become elongated, and broadened, while others are abbreviated or even obliterated. Polycystic kidneys are occasionally enormous; kidneys weighing 17 pounds have been observed

Coincident cystic disease of the liver occurs frequently in association with polycystic renal disease The cystic disease of the liver seldom is the cause of symptoms suggestive of hepatic disease Cysts of the liver do not usually attain great size, although occasionally they are large and it may be impossible to differentiate them from renal cysts Hepatic cysts may be observed without any accompanying renal involvement (see Diseases of the Liver, Chapter 13)

In this polycystic disease other organs besides the kidneys and liver may be involved Cystic degeneration of the ovaries, broad ligament, uterus, bladder, and epididymides may occur This fact indicates a single origin, perhaps congenital, of the condition.

Solitary cysts of the kidney probably are of acquired rather than of congenital origin. Occasionally multiple scattered solitary cysts are observed, but seldom are

The deeper situation of the left kidney is most often associated with delayed recognition of the disease. Bilateral tumors are rare

Hematuria is the first symptom; it is also the most frequent and the most important symptom. It may be painless and sudden in its appearance, and it may spontaneously disappear It may or may not recur At times it may be associated with renal colic, and the patient may pass cylindrical ureteral casts composed of blood and associated with severe pain situated in the course of the ureter. More commonly, however, there is just a dull ache in the flank. Continuous fixed pain in flank or back may be a symptom of large tumors

Weakness and loss of weight attend the progress of the disease. Fever is frequently observed with renal carcinoma In a few an unexplained fever is the only symptom. Fever is attributed to hemorrhage within the neoplasm and subsequent necrosis. Calcified deposits in the tumor visible in roentgenograms may represent the only diagnostic clue

When metastasis is present, the symptoms are referable to the organ involved This may be manifested by a spontaneous fracture of a long bone or the finding of metastatic lesions in a lung on roentgenologic examination Such lesions are found in about one third of the patients on the first examination. One half of the metastatic lesions are in the lungs, and the rest are in the bones, in the liver and in the brain.

On examination one half will have a mass in the flank or a palpable mass in the renal region by the time of the appearance of the hematuria A few patients are conscious of the mass or have had pain in the flank or along the course of the ureter. The mass is felt bimanually and is associated on palpation with deep inspiration. Coexistent prostatic hypertrophy may be found along with urinary frequency, lessened stream, urinary retention and blood clots in ureters, bladder or urethra.

The finding of variocele on the same side as the mass is frequent

Embryonal carcinosarcoma, or *Wilms's tumor* of the kidney, is one of the more frequent carcinomas of childhood It is a disease of infancy Rarely the tumor may occur in adult life, and it is then less malignant. Embryomas of this type are found equally in both sexes The tumors may be bilateral

These tumors may arise from any portion of the kidney As a rule, they grow rapidly, with large round or lobular, bosselated masses forward into the abdominal cavity.

Metastasis of embryonal carcinosarcoma is most often through the blood stream to the lungs and to the liver Lymphatic metastasis may occur to retroperitoneal and mediastinal nodes Involvement of the skeletal system is not frequent At times the tumor may grow directly through the renal capsule and involve adjacent organs

There are no signs of Wilms's tumor in its early stage Fever when present may be due to tumor necrosis or to hemorrhage within the tumor Hematuria occurs in 1 of every 10

On examination there is a mass in the abdomen or flank Pallor, weakness and loss of weight may be present with, or precede the finding of, the abdominal mass and always are present late in the disease Urinary symptoms are usually absent even late in the progress of the tumor

The diagnosis is established by pyelography and by the pressure of a mass in the side of the abdomen This mass is usually large, not tender, is rounded or lobular, and the transverse colon may be anterior to the mass if it is in the left kidney The tumor may or may not be fixed in the flank. The various other conditions presenting similar findings are carcinoma of the adrenal gland (sympathicoblastoma), chronic renal fibrosis, congenital obstructive hydronephrosis, congenital polycystic renal disease, and the retroperitoneal sarcomas of childhood

Carcinoma of the renal pelvis, arising from the specialized epithelial lining, is the same as the epithelial cancers of the ureter and the bladder. It occurs in both

On abdominal palpation, particularly if there are several distended cysts on the anterior surface of the kidney, the tumor may appear to be firm and solid

In men a *varicocele* of recent origin may occur on the left side, in association with marked enlargement of the left kidney, just as this condition occurs frequently with renal neoplasm

By the time, and often before, any symptoms of the renal disease appear, persistent *hypertension* is present In Schacht's series 61 per cent had systolic pressures of 145 mm of mercury or more In 20 per cent there was retinitis associated with retinal sclerosis In 31 per cent there was retinal sclerosis unassociated with retinitis In 6 per cent the patients had retinitis only, and without changes in the retinal vessels. In 43 per cent, examination of the ocular fundi gave negative results. It is evident, therefore, that the disease involves the entire vascular system

The specific gravity of the *urine* may be low and fixed Albumin, usually in small amounts, is present Microscopic evidence of hematuria and pyuria is often found (in Schacht's series in 180 cases, 94 per cent), in routine examinations of the urine Catheterized urine from either kidney often contains a variable number of pus cells This is apparently the result of inadequate intrapelvic drainage, caused by cysts compressing the pelvis or calyces

Normal excretion of phenolsulfonphthalein should not be regarded as excluding polycystic disease Excretion of phenolsulfonphthalein is often markedly reduced, whereas the value for blood urea is normal or only slightly elevated As the disease progresses, the concentration of blood urea increases

DIAGNOSIS The recognition of polycystic kidney is impossible without intravenous urograms or bilateral pyelograms The deformity of the renal pelvis as the result of polycystic disease is usually typical and easily recognized by the urologist It may, however, be unusual in outline and may simulate deformity seen with renal neoplasm so closely that differentiation is impossible If the renal pelves are shown to be normal, polycystic kidney can usually be excluded

The renal origin of the patient's symptoms may be first recognized in the course of routine study of renal function or urographically by intravenous pyelograms The condition may be confused with nephritis if no renal enlargement is present on palpation

After the disease is discovered, approximately half of the patients will live less than 4 years The remaining patients will live from 5 to 20 years The average age at death is 50 years.

The length of life will depend largely on the degree to which renal function is maintained The prognosis for the patient who is from 20 to 40 years of age is uncertain, since evidence of subnormal renal function usually is not marked until 40 years of age The patient observed from 40 to 60 years of age, who shows no evidence of diminished renal function, usually will live a life of normal length

Malignant Renal Tumors. The usual renal cancer is epithelial in origin, originating from the renal parenchyma or from the epithelial lining of the renal pelvis The latter, a specialized epithelium, is like the epithelium lining the ureter and the bladder, and all the tumors arising from this specialized epithelium are similar, whether from renal pelvis, ureter or bladder The tumors occurring from the renal parenchyma itself are specific tumors of that tissue

An occasional fibrosarcoma or leiomyosarcoma arises from the renal capsule These neoplasms are differentiated only by histologic study

Cahill classified renal tumors as follows (1) clear cell carcinoma, (2) granular cell carcinoma, (3) true hypernephroma (adrenal rests), (4) tumors in solitary cysts, (5) multiple papillary adenoma or carcinoma in sclerotic tubular cysts, and (6) mixed forms, among which the carcinosarcoma of infants (Wilms's tumor) is the most frequent

Parenchymal renal carcinoma occurs more frequently in men than in women in the ratio of 3 to 1. Both sexes are affected between 40 and 60 years of age

In an adult it is difficult to tell whether a stricture is congenital or acquired.

A megalo-ureter is uniformly dilated, the ureteral orifice being insufficient and allowing regurgitation of urine from the bladder If such a ureter is present and the bladder is filled with radiopaque fluid, the fluid flows up the affected ureter.

A diverticulum of the ureter is rare and may occur as a pocket which resembles a rudimentary supernumerary ureter The condition is distinguished from a cystic dilatation of the ureter.

The symptoms vary with the changes in the affected ureter and kidney, and the bladder. The patient may have ureteral pain due to the ureteral obstruction. There may be blood in the urine

Cystoscopic examination and ureteral catheterization with injection of a radiopaque medium reveal an abnormally large ureter

Ureteral Obstruction. Ureteral obstructions arise from lesions of the ureter or are due to pressure or invasion of some lesions outside the ureter. Obstructions of the ureters are thus classified as intrinsic and extrinsic, depending on their origin in reference to the ureter. They may be either strictures or obstructions of the lumen of the ureter.

Intrinsic ureteral obstructions may be classified as congenital and acquired.

Congenital Stricture. A congenital ureteral stricture is failure in development of a normal ureteral lumen. Strictures of this type are observed in the newborn and in children who have strictures without acquired urologic disease Similar strictures may be found in the presence of other malformations of the urinary tract.

The common congenital obstructing lesions are situated at or near the ureteropelvic or ureterovesical junction and at the vesical neck

Congenital obstructions at the ureteropelvic junction occur when there is too high an insertion of the ureter above the most dependent portion of the renal pelvis, or there is intrinsic narrowing of the ureteropelvic junction Obstructions at the ureteropelvic junction usually occur in young adulthood and are manifested by pain, recurrent pyelonephritis or a mass in the flank Congenital obstructions at the ureterovesical junction are bilateral

Congenital obstructive lesions at the ureterovesical junction may involve only the mucosa or may involve all the layers of the ureteral wall In the first group, the pressure of urine retained behind the small ureteral orifice causes a ballooning of the mucosa into the bladder so that ureterocele is produced Occasionally, a ureterocele may be of such proportions as to produce acute retention by obstruction of the vesical outlet In women it may extend through the urethra

Acquired Stricture. This type of stricture may be due to (1) inflammation, (2) stone, (3) trauma and (4) tumor The primary tumors of the renal pelvis and the ureter are described separately

Inflammatory lesions include infections by the colon bacillus and gram-positive cocci, and by the tubercle bacillus These inflammatory lesions of the ureter are usually part of a more general urinary infection

The common situations of nontuberculous inflammatory stricture are in the juxtavesical ureter, or the part of the ureter which passes through the wall of the bladder, and the part within the broad ligament, the pelvic brim and the ureteropelvic junction. The portion of the ureter in the vesical wall or adjacent thereto is often involved as the result of chronic cystitis, which not only infiltrates the ureteral wall but also may constrict the ureteral orifice

Stone may produce ureteral stricture by impaction and injury to the ureteral wall

Trauma, which may be inflicted during childbirth, a surgical operation, or cystoscopic procedures, may be followed by stricture

Physiologic intrinsic transitory ureteral strictures may occur during pregnancy,

sexes, slightly more frequently in men than in women, and equally in both kidneys It is more likely to occur in persons in the elderly age group than in younger persons

Renal pelvic tumors have been reported as associated with pelvic calculi and with long-standing inflammatory processes There does not seem to be any recognizable association with congenital abnormalities in the development of renal pelvic tumors

Tumors of the renal pelves arise from specialized epithelium of mesodermal origin They are classified as (1) papilloma, (2) papillary carcinoma, (3) squamous cell carcinoma and (4) undifferentiated carcinoma.

About two thirds of all tumors of the renal pelvis are papillary They may be single or multiple They are villous or wartlike growths similar to those found in the bladder and may be associated with similar tumors found in the bladder or ureters More than half of the papillary tumors of the renal pelvis are malignant

Squamous cell carcinoma in the renal pelvis is less frequent than the papillary type It occurs with irritant lesions such as infection, calculus, ureteritis cystica and leukoplakia Ulceration is common These tumors are less vascular than the papillary tumors

Infiltrating undifferentiated carcinoma occurs but is less frequent than carcinomas of other types

Tumors of the renal pelvis tend to metastasize down the ureter as well as through lymphatics to the retroperitoneal lymph nodes. From these nodes they disseminate to lungs, liver, adrenal glands and bones

The constant symptom of tumor of the renal pelvis is hematuria Pain may occur but is not constant or frequent If the bleeding is profuse there may be renal colic from a blood clot obstructing the ureter If obstruction of the pelvis occurs there may be pain in the flank

In only a small number of patients does a palpable tumor develop, a concomitant hydronephrosis is the cause of the palpable mass The mass may disappear after the passage of obstructing material General symptoms, consisting of loss of weight, strength and appetite, attend the late stages of the disease Vesical symptoms of burning, frequency and dysuria may be present if there is an associated infection

Tumor of the renal pelvis is diagnosed by cystoscopic examination and retrograde pyelograms

DISEASES OF THE URETERS

Congenital malformations of the ureters are closely associated with those of the kidneys Absence of a ureter occurs in cases of renal agenesis—solitary kidney. In such cases, cystoscopic study reveals absence of the corresponding ureteral orifice

In duplication of the ureters the malformation may be complete or incomplete. If there is complete duplication, there are two ureteral orifices each leading to its corresponding ureter and renal pelvis The corresponding double kidneys are often fused

If the ureteral duplication is incomplete, there is only one ureteral orifice and one terminal portion of the ureter At varying distances from the bladder the ureter divides, each resulting ureter pursuing an independent course to the corresponding half of a double or fused kidney

The ureteral orifice may be ectopic, prolapsed (ureterocele), stenosed, or dilated, or it may present various congenital malformations It is difficult to determine whether some of these conditions are congenital or acquired

The ureter may open outside of the bladder—in the urethra, vestibule, vagina, and, very rarely, the uterus, tubes or rectum—or it may end blindly, without any external opening. It may be an opening of a supernumerary, atrophic kidney. The commonest situations for these ectopic openings are the urethra, vestibule, and vagina, causing urinary incontinence

The diagnosis is made by localizing the stream of urine away from the usual sites for its opening in the bladder and catheterizing its opening Intravenous and retrograde urography reveal a normal bladder with one normal ureter and kidney.

Anomalies of the ureteral lumen consist of congenital stricture, valves, megaloureter, and diverticulum.

disease of the bladder may also produce complete anuria by occluding both ureters.

Incomplete Ureteral Obstruction. Ureteral lesions are much commoner in women than in men, for the female pelvis is subject to the many diseases of the adnexa, to childbirth injuries, infections incident to childbirth or abortion, and cervicitis.

The general effect of obstruction of the ureter, whether it is complete or incomplete, is urinary stasis. If obstruction is partial and the ureteral lesion remains stationary, the condition may be present for years. Renal damage is hastened if an infection or stone develops.

Partial obstruction of the ureter interferes with the expulsion of the urine, raises the intra-ureteral pressure, causes hypertrophy of the ureteral muscle, and may make ureteral peristalsis painful, owing to spasm and irritation The continuation of this pressure also produces ureteral dilatation (hydro-ureter), blunting of the calyces, hydronephrosis, and stasis of the urine Hydronephrotic kidneys may contain liters of urine; some are large enough to fill the whole abdomen. In such cases the renal parenchyma becomes a thin shell of tissue with little or no function remaining

The indirect effects of incomplete ureteral obstruction predispose to infection and formation of stones It is impossible to overcome urinary infection so long as there is poor urinary drainage The combined effect of urinary stasis and infection rapidly destroys renal function and reduces the kidney to pyonephrosis

The condition may be asymptomatic, or there may be local or general symptoms

Asymptomatic obstruction is often discovered by intravenous urography performed in a routine search for the cause of obscure symptoms. Such a discovery may explain toxic phenomena and obscure constitutional symptoms such as gastrointestinal disturbances, indigestion, gas, anorexia, headache, loss of weight, nervousness, low-grade fever, and other disturbances

The commoner types of symptoms are pain, colic, vesical symptoms, pelvic or vaginal discomfort, and dysmenorrhea These symptoms vary in intensity, without relation to the degree of obstruction

The diagnosis is made by the evidence of ureteral obstruction revealed by cystoscopic examination, ureteral catheterization, roentgenologic examination of the kidney and ureter

The diagnosis of ureteral obstruction often depends on the awareness that such a condition may be present to cause the symptoms

Ureteral Fistulas. Ureteral vaginal fistulas or ureterocutaneous fistulas may be of congenital or of acquired origin. The common form of opening of a ureter to the exterior of the body is observed in extrophia of the bladder The ureteral opening in the congenital ureterovaginal fistula is another form of ectopic ureteral opening due to prenatal influences

In the acquired type the continuity of the ureter has been interrupted and the ureter establishes a new opening into the vagina Acquired fistulas of this type usually are the result of operative injury, especially during panhysterectomy. Ureterovaginal fistula may also follow vaginal ureterotomy for stone if the distal part of the ureter is obstructed Malignant tumors may cause ureterovaginal fistula

Ureterovaginal fistulas are diagnosed by searching the vagina for the opening of the ureter Cystoscopic examination reveals the presence of but one active ureteral orifice Intravenous urogram reveals the course of the media from the kidneys down the ureters, one to the bladder and the other elsewhere

DISEASES OF THE BLADDER

When fully distended, the normal bladder contains approximately 500 ml Its capacity varies much, and it is capable of great distention without rupture In cases of retention of urine it may reach up to the umbilicus and contain 1,000 ml

when there is hypertrophy and increased rigidity and thickness of the terminal portion of the ureter

Extrinsic ureteral obstructions may be congenital or acquired

Congenital Obstruction. Fascial bands along the course of the ureter, especially near the ureteropelvic junction, occasionally cause obstruction. Supernumerary or aberrant renal blood vessels have the same effect. Ptosis of the kidney may produce kinking of the proximal portion of the ureter and thus produce ureteral obstruction. This is a very rare cause of renal colic (Dietl's crisis) and hydronephrosis

Acquired Obstruction. The causes of extrinsic ureteral obstruction include pelvic tumors, pelvic inflammatory lesions, prolapse of the uterus, surgical trauma, scars following irradiation, pregnancy, fascial bands, aberrant blood vessels, nephroptosis, or any condition which compresses, constricts, kinks or narrows the ureteral lumen so that the flow of urine is impeded

Carcinomas of the cervix, bladder or colon are frequently associated with ureteral obstruction. These tumors obstruct or compress the ureter by invading, surrounding or infiltrating the ureteral wall and compressing it.

Constriction of the ureter by tumor produces hydro-ureter, hydronephrosis, and atrophy of the kidney Infection may supervene. Infection is a factor in initiating the terminal ureteral colic, progressive renal insufficiency, and eventual uremia which are common causes of death in pelvic malignant disease.

The combined effect of the pressure of the gravid uterus, and hypertrophy of the trigonum, vesical wall, and sheath of Waldeyer with constriction of the vesical ureter often causes ureteral dilatation

Prolapse of the uterus is often accompanied by ureteral obstruction and dilatation.

Complete Ureteral Obstruction. Ureteral obstruction may be complete or incomplete It may be unilateral or bilateral It may be acute or chronic Complete ureteral obstruction is uncommon, as compared with the partial obstruction

Accidental ligation of the ureters during surgical operation and extensive pelvic malignancy are the causes of complete obstruction of both ureters.

Because of anuria bilateral operative injuries of the ureters are recognized very soon after operation Surgical treatment consisting of provision of urinary drainage is urgent because, if renal drainage is not provided, the patient dies of uremia within 2 weeks

In some unilateral ureteral ligation does not cause symptoms or fistula The kidney ceases to function and atrophies In instances in which the ureter is injured, pyelonephritis, hydro-ureter, or stricture is the eventual consequence of trauma

Cystoscopic examination reveals a normal ureter on one side The opposite ureter does not drain urine, the ureter is completely obstructed and will not allow a ureteral catheter to pass beyond the situation of the injury.

Occasionally a stone may completely obstruct one ureter Complete ureteral obstruction may be preceded by incomplete occlusion of long duration A hydronephrotic kidney which has been caused by incomplete obstruction may completely occlude a ureteropelvic junction as its weight pulls it caudad

The effect of complete unrelieved ureteral obstruction is death of the kidney If the obstruction is relieved without undue delay, under proper care and favorable circumstances the functional recovery may be complete, although such recovery usually requires months

The symptoms of bilateral acute obstruction of the ureters were discussed in connection with the description of uremia (see p. 745).

The diagnosis of complete bilateral ureteral obstruction is usually self-evident, since there is complete anuria If complete anuria occurs after a pelvic, colon or gynecologic operation, it is generally due to operative injury to both ureters It may likewise develop suddenly in persons who have bilateral renal calculi Malignant

of normal children and adults testifies how psychic tension may influence the functions of the autonomic nervous system and thus disturb its reflexes.

It is pointless to enumerate the uses the child or the adult may, more or less unconsciously, make of this debility. The physician cannot agree with solicitous parents or psychoneurotic patients concerning the alleged influence of adenoids, phimosis or a tight meatus in causing enuresis

On examination it is realized that the normal child is unable to distinguish between imperative urination and enuresis Diabetes, juvenile tabes, spina bifida, urinary tuberculosis, stone, megalo-ureter, sclerosis of the vesical neck and urethral valve are rarely found to be the cause for enuresis Urine, renal functional studies, and the sacral vertebrae (as revealed on roentgenograms) are usually within the limits of normal The intelligence quotient may be low.

Spina bifida occulta, confined to the first sacral vertebra, is extremely common *and usually does not produce enuresis The child simply and painlessly, though* to his great shame, wets the bed.

Interferences With Nervous Control of the Bladder. The bladder is supplied with autonomic (sympathetic and parasympathetic) and cerebrospinal nerves. Diseases or injury to these nerves separately or in combinations will disturb its emptying.

Section of the sympathetic nerves causes a transient disturbance in urination but this usually, in time, passes away Section of the sacral nerves causes a complete loss of voluntary micturition In time, if the bladder is otherwise healthy, the so-called isolated bladder is established Under this circumstance micturition can be incompletely performed by application of abdominal pressure as by flexion of the body There is always left from 100 to 300 ml of urine after such urination

Efferent control of the bladder is disturbed by lesions in the vicinity of the pyramidal tracts The patient is conscious of all events occurring in the bladder but he cannot initiate or control micturition This sort of disturbance of micturition occurs in tabes dorsalis, multiple (disseminated) sclerosis, syringomyelia, and early compression of the cord by a tumor The so-called cord bladder of tabes dorsalis is this type of disturbance.

In obstructions to the outflow of urine from the bladder which may occur in prostatism, sclerosis of the vesical neck and atonic sphincter with a weak detrusor muscle, overdistention causes expulsion of urine in small quantities and often a more or less constant dribbling of urine.

The first symptom of tabes dorsalis or multiple sclerosis may be dysfunction of the bladder In tabes dorsalis bladder dysfunction may be expressed by frequency of urination or impairment of renal function or cystitis, exhibiting retention due to relaxation of the vesical muscle The capacity of the bladder is increased and its mucosa is trabeculated early The neck of the bladder is open This open neck may be seen with the direct vision posterior urethroscope and shown by cystogram or urethrogram

The external sphincter alone intervenes to retain the patient's urine in the neurogenic bladder and it is usually a weakness in this rather than the level of the lesion in the cord that causes incontinence of urine.

The diagnosis of the cause of the vesical symptoms and the renal deficiency in the tabetic patient is obvious. The diagnosis is difficult when tabes and hypertrophy of the prostate occur in the same patient, or when the retention occurs in one who does not show the classic reflex changes

In the absence of prostatic hypertrophy or bar, the tabetic bladder is differentiated from the sclerosis of the vesical neck by cysto-urethrographic or urethroscopic examination Cystometry is used to differentiate the tabetic bladder from the atonic bladder

The diagnosis of disturbances in the [illegible] ... of sensory

or more, whereas if its walls are thickened, it may be contracted and hold only a few ounces. The shape of the bladder is dependent on the amount of dilatation and its attachments. The distended normal bladder is always oblong; the long axis corresponds to the long axis of the spinal column.

A distended bladder interferes with the proper execution of a pelvic examination The bladder should always be emptied before examination of the pelvis, since during this examination no definite decision is made, if the bladder is not empty, in regard to the nature of a pelvic tumor that may be present.

Congenital Malformations of the Bladder. The principal malformations of the bladder are absence, *doubling, diverticula, and exstrophy.*

Absence of the bladder and double or septate bladder are excessively rare

Diverticula of the bladder occur more frequently in men than in women and may be congenital or acquired. Those that appear in young persons, without any evidence of urethral obstruction, are called congenital, those that appear in later life, with evident urethral obstruction, are called acquired

Diverticula *may resemble double bladder, patent urachus, or trabeculations that are* the result of cystitis, obstruction and hypertrophy of the vesical musculature

Vesical diverticula may not cause symptoms unless the diverticulum has a narrow opening into the bladder, with poor drainage The symptoms when present may result from infection, calculi and tumors in the diverticula.

In exstrophy the anterior wall of the bladder and the adjacent part of the abdominal wall are *missing The result is that the posterior wall of the bladder, the trigone,* and ureteral orifices lie exposed on the abdominal wall, forming a red, sensitive, and often bleeding mass

Multiple malformations may accompany exstrophy, such as widely separated pubic bones and recti muscles. In the more profound congenital disturbances there may be prolapse of the rectum, rudimentary bicornate uterus and septate vagina There may be atresia *of the anus and the rectum may open into the* exstrophied bladder. The ureteral orifices are generally found on the lower part of the exstrophied mass.

Congenital obstructions to the vesical outlet vary widely The two common types are (1) elevation of the posterior internal sphincteric area simulating the median bar in adults and (2) contracture of the internal vesical orifice These occur in both males and females. The least common type is congenital prostatic urethral valves Whatever the immediate lesion, the syndrome of *uncomplicated obstruction* of the vesical neck is fundamentally the same as is observed in men who have prostatism (see p 431)

Disturbances in Emptying of the Bladder. When the bladder of a baby fills sufficiently to excite some mild sense of distention, it empties During the first years of life the bladder thus empties any time there is distention either day or night If a functional lack of control persists into late childhood or adolescence it is termed nocturnal enuresis or *bed wetting.*

Enuresis differs from *incontinence* of urine such as occurs after perineal prostatectomy. Enuresis differs, too, from false incontinence, the overflow of a constantly full bladder, which is seen before prostatectomy.

Imperative urination demands instant emptying of the overdistended organ of the neurotic patient or the bladder is tortured by the cramp of cystitis

Atony applies to the tired overdistended vesical muscle which may develop for example during the postpartum or the postoperative convalescences

Overflow, false incontinence, is inseparable from atony.

The functional *enuresis of childhood* is a persistence of the infantile autonomic nervous system control of the bladder without cerebral influences The child wets himself by day only under the stress of fear or great excitement unless he has a very low intelligence quotient. Normal or even intellectual adolescents and adults may rush to the toilet every few minutes before a public appearance This behavior

mucous membrane. The inflammation may be situated in any part of the bladder or over the entire organ. The bladder dilates incompletely and distention is painful. The base and the trigone are involved more than other parts. Inflammatory thickening of the mucosa may be present. This condition, called bullous edema, surrounds the urethral orifice, continues down the posterior urethra, and may be the focus of recurring cystitis. The bladder is often contracted in chronic cystitis. The infection is not especially localized around either ureteral orifice, thus distinguishing it from infections that descend from the kidney, such as tuberculosis

DIAGNOSIS The diagnosis is established tentatively by the history and the presence of pyuria. In simple acute cystitis a cystoscopic examination would be extremely painful. In general, it is well to avoid instrumentation during the acute phase of a urinary infection. When the infection becomes subacute or chronic, however, a trained urologist should see inside the bladder.

Tuberculous Cystitis. Tuberculous cystitis is described with renal tuberculosis (page 759).

Chronic Interstitial Cystitis. (*Hunner's Ulcer*). Chronic interstitial cystitis occurs preponderantly in women, often in those beyond the menopause. The disease has been observed in men It is characteristically situated in the vertex or dome of the bladder It is one of the relatively uncommon lesions of the bladder.

Urologists describe three types of lesions: a diffuse, a linear and an ulcerous type.

There is constant and often intense pain in the bladder, increased by micturition and exertion. Frequency is often intense, as evidenced by voiding every 15 minutes, both day and night.

If the patient has passed the menopause and she has chronic severe vesical symptoms of many years' duration and the urine is microscopically clear, the diagnosis is likely a chronic interstitial cystitis Cystoscopic examination establishes the diagnosis. The capacity of the bladder is often 150 to 200 ml Cultures of the vesical urine and cultures of the vesical wall are sterile.

Unusual Forms of Cystitis. When the bladder is covered by a layer of urinary salts, the disease is called *encrusted cystitis.*

In proliferative cystitis the epithelium is increased and may resemble papillary new growths A form of proliferative cystitis is *cystitis granulomatosa* The granulation tissue resembles multiple polyps or a neoplasm This form of cystitis is also designated *granular* or *polypoid* Biopsy is routine in these cases A transformation of the surface epithelium into glands is known as a *glandular cystitis* and this is similar to *cystitis cystica,* in which the wall of the bladder is covered by cystic structures Cystitis cystica is common around the internal urethra and trigone Cystic changes similar to cystitis cystica have been observed in the ureter and the renal pelvis The condition characterized by enlarged, infected lymph follicles in the wall of the bladder is known as *cystitis follicularis.*

Leukoplakia of the bladder and occasionally of the renal pelvis is characterized by thickened raised white patches Its cause is unknown A specimen for biopsy is always taken of any area of unusual or suspicious appearance to rule out malignancy.

Syphilis of the Bladder. The described lesions of syphilis of the bladder are either secondary or tertiary. The spirochete has not been found Finestone collected reports of 158 cases. Of these he accepted one report of a case in which presence of syphilis was microscopically proved, and he added reports of 2 more proved cases

Diseases of the Bladder Associated With Trauma. *Herniation of the Bladder.* The bladder is subject to three types of herniation· (1) prolapse through the urethra of the female, (2) bulge into the vagina when the pelvic floor is weakened, a cystocele, and (3) formation of part of the contents of a femoral or ingu[illegible]ia.

nerve functions and the deformity of the vertebrae revealed on physical and roentgenologic examinations

Transverse myelitis or fracture of the spinal column with complete loss of nervous function below the point of fracture or disease results in complete paralysis of the bladder and complete anesthesia of the bladder as well. The patient who has complete loss of spinal function has far greater loss of nervous control than the tabetic patient and stands the catheter far less well.

In order to prevent possible serious consequences which may follow the introduction of a catheter into the bladder of a patient who has transverse myelitis or traumatic paraplegia, it may be necessary to administer sufficient narcotic to prevent discomfort from pelvic fullness. Within 4 days the distended viscus begins to overflow Within 10 days or 2 weeks the automatic bladder will have become established and excretory pyelograms will show that the viscus contains little urine.

Urinary Retention in Women. Urinary retention in women is not common. Estimation of its relative incidence in the sexes is difficult, but urinary retention occurs many times more frequently among men than among women In most cases, if true *neurogenic dysfunction* is excluded, the cause is obscure. Such factors as pelvic operations, repeated pregnancies, infection, and urethritis seem to contribute. In some instances trabeculation of the bladder may be present, but just as often the appearance of the vesical neck is not unusual. Hyperplastic-appearing vesical necks often are reported in women who have normal vesical function and do not have urinary retention. Transurethral resection of the vesical neck, removing muscular tissue from the entire circumference, will eliminate the residual urine in most cases

Cystitis. The term cystitis is applied to several groups of diseases of the urinary bladder These are (1) acute and nonspecific cystitis, (2) tuberculous cystitis, (3) chronic interstitial cystitis and (4) other disorders which include unusual clinical types that may not be pathologically distinct or categorically classified.

A primary acute nonspecific cystitis is an uncommon disease It has somewhat different causes in women than in men. In children it is often associated with congenital malformations of the urinary and genital organs

The female bladder becomes infected from sources within the urethra such as an acute urethritis, infections in Skene's glands, urethral trauma, strictures, diverticula, caruncle and carcinoma. A cystitis may follow urethral trauma from foreign bodies introduced into the bladder or from sexual intercourse in a virgin or in a woman who has long abstained from intercourse who has passed the menopause. An acute cystitis may occur in those who have cystocele, rectocele, cancer of the cervix, uterus, bladder or infections in the pelvis which extend to involve the bladder. Pyelitis unless tuberculous in nature does not often cause cystitis The prevailing organisms found in acute cystitis are those which commonly cause urinary infections in general

Acute cystitis occurs much less frequently in men than it does in women It is in men as in women usually secondary to a urethral disorder and commonly has extended from the prostatic urethra, from the kidney as in tuberculosis of the kidney or extended from the pelvic organs A diverticulitis or a carcinoma of the colon often extends to involve the urinary bladder

Symptoms The symptoms of nonspecific cystitis are frequency, pain on voiding, pain in the suprapubic area, backache and low-grade fever. In the type called hemorrhagic cystitis the patient complains of hematuria. The constitutional symptoms are few and inconstant.

Examination. The acutely inflamed bladder should not be examined cystoscopically until the inflammation has somewhat subsided.

Acute nonspecific *cystitis* is *described* by the urologist as a hyperemia of the

vagina which begins 8 to 20 days after an extensive gynecologic operation. The incontinence is incomplete, part of the urine being passed normally with perfect control by the urethra, the urine from the injured ureter draining constantly and uncontrollably from the vagina.

In instances of vesicovaginal fistulas from various causes often the incontinence of urine is complete. The urine passes from the bladder into the vagina as soon as it leaves the ureter. The patient never voids through the urethra.

If the fistula is small there may be no incontinence while the patient is in certain positions, for instance, sitting or lying down

Urine irritates the vaginal mucosa and perineal skin. The epithelium of the vagina, labia, perineum, and buttocks soon becomes red and inflamed, and may ulcerate. It makes very little difference how small the fistulous opening is; if it leaks urine it is as annoying as a large opening. The troublesome symptom is a constant drainage of urine.

Vesicovaginal fistulas are diagnosed by examination of the vagina by means of the vaginal speculum and identifying the fistulous opening from the bladder by its drainage of urine. This finding must be verified by cystoscopic examination.

Distention of the intact bladder with methylene blue solution reveals that the bladder does not leak and that none of the methylene blue solution appears in the vagina or on the outside of the body. In some instances the methylene blue solution may drain from the bladder through a fistula to the vagina or to the outside. Bladder fistulas may form to the outside of the body after traumatic piercing, injuries of the bladder due to violence, obstruction of the ureter or urethra, tuberculosis, or malignant disease of the ureter or bladder. During the course of osteomyelitis of the pelvis or femur, sinus tracts may form which communicate with the urinary system

Tumors of the Bladder. Tumors of the bladder are often carcinomas or potentially so. Carcinoma of the bladder occurs in middle age or later and is commoner in men than in women

Urologists classify vesical tumors as papilloma, papillary carcinoma, and infiltrating carcinoma These include most of the tumors of the bladder.

There are, however, secondary types of vesical tumors which include those involving the bladder and having their origin in the cervix, endometrium, ovary, vagina, or sigmoid

Cancer of the bladder, like cancer of the lungs, has displayed an increase in incidence in recent years The cause for this increase in incidence is not known Observations by Henry, Kennaway and Kennaway in England suggest that occupational contact not only with aromatic amines but possibly also with tar, pitch and mineral oil seems to produce an increased liability to cancer of the bladder. Recent observations in experimental animals and man support the contention that carcinogenic substances excreted in the urine are responsible for the development of certain cancers in the bladder

PATHOLOGY Papillomas include the benign papilloma and the papillary carcinoma. These are the commonest types of vesical tumors Some papillomas are probably malignant from the beginning and others are always benign The malignancy or benignity of a papilloma is hard to determine. Many papillomas that are benign recur locally after removal and are easily transplanted over the whole bladder In the gross, the thickness of the pedicle, whether the tumor is pedunculated or sessile, and the presence of induration or nodular thickening of the tissue around the base are criteria of malignancy

SYMPTOMS Hematuria is the important symptom which is constant throughout the disease The situation of the tumor may cause difficulty of urination by intermittently occluding or actually infiltrating the internal urethral orifice. Blood clots too large to be voided are the commonest cause of urethral obstruction in cases

Rupture of the Bladder. Trauma of the urinary organs, particularly of the bladder, is common, largely because of injuries received by persons pursuing domiciliary tasks, by passengers in automobiles that are involved in accidents, and by persons engaged in athletics.

Any injury of the bony pelvis or blow on the abdomen may rupture or tear a full bladder. The bladder may be injured by a cystoscope or by cystoscopic procedures. The cystoscope in careless hands may perforate a bladder. A hole may be burned in the bladder by fulguration or cut out by a biopsy punch

Traumatic Rupture of the Bladder. Fracture of the pelvis or abdominal contusions may tear the bladder, producing (1) extraperitoneal rupture or (2) intraperitoneal rupture.

In rupture, either extraperitoneal or intraperitoneal, there are passage of bloody urine, or anuria, pain in the pelvic region, and shock

The history of inability to void after an accident, or the passage of small amounts of bloody urine, is important

In extraperitoneal rupture of the bladder examination reveals sensitiveness around the bladder, and occasionally there is a mass. Peritoneal irritation is present, and often a spreading peritonitis develops. The evidence of injury to the bony pelvis or the presence of tenderness in the region of the bladder or lower part of the abdomen is confirmatory. Bloody urine, obtained by catheterizing the bladder, indicates injury to the urinary tract.

The injection of a measured amount of sterile fluid into the bladder is occasionally a helpful diagnostic step. If the full amount which was injected is recovered, there is probably no gaping hole in the bladder.

The diagnosis and localization of the injury are established by local examination, catheterization, cystoscopic examination, injection of air, and roentgenograms.

Cystoscopy is the surest method of diagnosis if the patient's condition will permit the procedure.

If the bladder opens into the peritoneal cavity, injected air escapes into the abdomen. With the patient sitting upright, the pneumoperitoneum is evident on a roentgenogram, the air bubble being visible under the diaphragm.

Urinary Fistulas. There are many possible variations of these fistulas, such as urethrovesicovaginal fistula, vesico-ureterovaginal fistula, vesicopelvic-vaginal fistula, and ureterocervical-vaginal fistula (see Anorectal Diseases, Chapter 7)

Unilateral postoperative injuries of the ureter may be the direct consequence of a surgical accident such as cutting, clamping, ligating or crushing the ureter, or they may be the result of interference with the blood supply of the ureter, infection following operation, or necrosis from ligation and constriction of adjacent tissues

Postoperatively, after cystotomy, ureterotomy, pyelotomy or nephrotomy, the incision may drain urine.

Intravenous urograms reveal a normal kidney and ureter on one side, and a normal bladder On the injured side the ureter is generally dilated, the kidney hydronephrotic.

Vesicovaginal and Vesical Fistulas. The vesicovaginal is the commonest vesical fistula. There are congenital forms of vesicovaginal fistulas which usually are surgically repaired before adulthood is reached Spontaneous formation of vesicovaginal fistulas may be incident to ulceration around stones or foreign bodies which penetrate the wall of the bladder, infections which tend to ulcerate, such as ileitis or diverticulitis of the colon and tuberculosis, and radium burns. A sharp surgical knife in an untrained hand may be the cause of a urinary fistula Vesicovaginal fistula may be due to malignancy arising in the vagina, bladder or pelvic colon

Postoperative vesicovaginal fistula occurs after extensive dissections of the base of the bladder, infections, or the pressure of drains

The first indication of a vesicovaginal fistula is the presence of urine in the

of vesical tumor Painful and frequent voiding from a secondary cystitis, and incontinence and fistula, especially vesicovaginal fistula, are often an attending complication

Secondary to ureteral obstruction and infection, the kidneys may become infected. There is pain in the course of the ureters and in the kidneys, and fever, toxemia and symptoms of renal insufficiency supervene

There is hardly any other condition which produces as many varieties of physical torture as a tumor of the bladder There are the constant symptoms of cystitis, acute pain of vesical overdistention, suprapubic pain, backache, ureteral and renal pain, sciatic pain, abdominal pain due to reflex gastrointestinal disorders, visceral pain due to metastasis, and many other types of pain and distress.

EXAMINATION Bimanual palpation of the bladder, by rectum and by vagina, is helpful, but must be done carefully to avoid breaking the tumor The important observations on physical examination are the size of the mass and its movability when the tumor is very large

DIAGNOSIS The symptoms alone are usually sufficient for making the diagnosis An objective diagnosis requires a cystoscopic examination and biopsy Biopsy of tumors of the bladder is not wholly innocuous Removal of a small piece with a fine cautery seals the tissues and is not so dangerous as some of the methods without hemostasis.

Cystographic examination is done as a part of the routine intravenous urographic study. It records a permanent picture of the capacity of the bladder and the extent of the deformity of the vesical wall and, to a large measure, the functional activity of the kidneys

There are three methods of treatment of malignant disease of the bladder: fulguration, surgical excision, and irradiation

The treatment of vesical tumors has often been unsatisfactory A survey of the subject was conducted by the American Urological Association and reported in 1939 (Orr, Carson, and Novak) This showed that the treatment of more than 26,000 malignant growths of the bladder by 267 urologists in America resulted in five-year cures in only 15 9 per cent, and that five-year cures are not always permanent

The *blood platelets* are produced by fragmentation or segmentation of the megakaryocytes of the bone marrow.

It is evident from the foregoing that in the circulating blood there are series of formed elements: the leukocytes, the erythrocytes and the platelets The leukocytes are composed of (1) the granulocytic cells arising from the bone marrow, (2) the monocytes, which arise from the reticuloendothelial cells and (3) the lymphocytes arising from lymphoid tissue. The platelets are segmentations of the megakaryocytes of the bone marrow.

The foregoing discussion on the origin of the blood cells was made with cognizance of the fact that there is still not full agreement as to the origin of the various cells of the blood There are two theories in regard to the origin of the individual cells of the blood, namely, the monophyletic, and the polyphyletic. According to the monophyletic theory all blood cells, including the erythrocytes, arise from the lymphocytes or from the lymphoid tissues According to the polyphyletic theory the erythrocytes and the different kinds of leukocytes are derived from two, three or more parent cells (blast cells). This theory embraces all gradations of belief. There are those who think that there is a stem cell for the erythrocyte and one for each of the leukocytes

There are neounitarians who see truth in all of the theories of the origin of the blood cells and wish to combine these into one theory

These theories are of diagnostic importance in regard to the nomenclature of the cells

Nomenclature of the Blood A committee for clarification of the nomenclature of cells and diseases of the blood and blood-forming organs sponsored by the American Society of Clinical Pathologists and the American Medical Association has agreed that the choice of preferred terms shall not be based on historical priority or common usage but, in general, shall represent the simplest, clearest and most descriptive terms possible. Consistency between related terms is considered essential The committee has given detailed consideration to terminology in the erythrocytic, lymphocytic, granulocytic, monocytic, plasmacytic and thrombocytic series of cells The committee has co-ordinated its work and co-operated with representatives of *Standard Nomenclature of Disease and Operations*, of the American Medical Association, in order that proposed changes may be incorporated in that publication

So far as is possible in the present limited description of blood diseases, the *Standard Nomenclature of Disease and Operations* is followed

DISORDERS AFFECTING THE TOTAL QUANTITY OF BLOOD

Normal Values The blood has a specific gravity of 1 052 to 1 063 and viscosity of 3 5 to 5 4 These values are slightly higher in men than in women or children

The blood in healthy adults comprises about 6 to 8 per cent of the body weight Normal blood volume averages 80 to 100 ml per kilogram of body weight. This range of 20 ml. variation is accounted for in some measure by variations in height, weight, and surface area

Generally the total blood volume per unit of surface area is high in muscular and obese persons, and low in thin persons In terms of units of body weight, the blood volume is high in muscular and thin persons, low in obese persons, and greater in men than in women The plasma volume of the two sexes differs but slightly

The volume of blood in circulation in health is maintained rather constant However, it is not a static quantity There are continual additions to the circulation and losses from the circulation by the passage of water, salts and nonprotein nitrogenous products back and forth into and out of the blood stream.

Various components of blood may act independently and often do so. Water may go into or out of the blood without corresponding movements of electrolytes, proteins or other substances in it Changes in the total mass of circulating blood cells may occur unrelated to alterations in plasma volume.

Many small variations of the values for blood volumes cannot be accounted for by

12

DISEASES OF THE HEMIC SYSTEM

The hemic system includes the blood, the bone marrow and the cells reticuloendothelial system which persist after birth

The blood is a fluid medium within which are suspended the cells The cells separated from their medium by centrifuging freshly drawn blood to which hepa been added The supernatant liquid thus separated is the plasma. Separation of t and the fluid medium by allowing the blood to clot and then centrifuging proc liquid, the serum

The plasma contains 90 to 92 per cent water The remaining 8 per cent is which contain 7 per cent proteins and 0 9 per cent electrolytes and the rest is co of neutral fats, glucose and many other substances

The plasma is a vehicle for carrying the blood cells but it has many and im functions not attributable to its cellular content It transports nutriments, ex products, hormones, antibodies, enzymes, and elecrolytes and aids in the maint of body temperature, to mention but a few of its functions

The plasma participates in some diseases of the hemic system as well as bei marily responsible for some of the hemorrhagic disorders, for instance, hemoph

When the blood is heparinized and the solids separated from the plasma th contains the erythrocytes, the leukocytes and the platelets These cellular element from the bone marrow, the reticuloendothelial cells and the lymphoid tissues

The *bone marrow* is composed of (1) the red cellular marrow in which bloo are formed and (2) the yellow marrow, which begins to replace the red marrow time after birth and advances until by the time of full bone growth in the early tv it has replaced the red marrow in the long bones Thenceforward, with the adv years, the yellow marrow makes but little more progress The red marrow rema the ribs, sternum, vertebral bodies, pelvis and skull, and from these foci the great of circulating elements of the blood is produced Yellow marrow does not produce

The cells of the postnatal reticuloendothelial system possess phagocytic fun These cells are identified as clasmatocytes, hemohistioblasts or macrophages by phagocytic properties and thus the ingestion of the particulate matters which co the specific supravital stains Through such staining these cells are known to be posed of two groups, namely, *fixed* cells and *wandering* cells. These designations d on whether the cells are found fixed in their usual situations in the connective reticula of the spleen, lymph nodes or bone marrow, or lining the blood sinuses marrow or liver (Kupffer's cells), or whether they are found in increased numb the site of an inflammatory reaction In the former situations they are fixed ce the latter they are wandering cells It is one function of these cells to phagocytize nants of erythrocytes and to remove discarded erythrocytes from the blood stream spleen contains many reticuloendothelial cells and it therefore is singularly conc with the function of the removal of aged erythrocytes from the blood stream.

There are blood cells which regularly arise from the reticuloendothelial syster instance, the *monocytes* of the circulating blood

Lymphoid tissue is present in all parts of the body. This tissue may occur diff as small masses, compactly, as in the simple lymph nodes, or in larger conglome as in the complex nodes and in the spleen The *lymphocytes* of the blood stream from the undifferentiated premature reticular cells of the stroma of lymphoid tiss

The *erythrocytes* and the *leukocytes* of the *granulocytic series* arise in the parts of the bone marrow. It seems that the granulocytic cells originate extravascu rather than within the capillaries as do the erythrocytes

Clinical shock in 9 of every 10 cases is produced by blood loss and thus oligemia. The fundamental feature of oligemic shock was established by Norman M. Keith.

In oligemic shock there is a reduction of blood volume so that the veins are not properly filled and consequently a decreased quantity of blood is returned to the heart. Owing to a lessened supply of blood the cardiac output is decreased, and the blood pressure thereby is lowered, inducing carotid sinus reflexes and air hunger. As compensatory mechanisms there are accelerated heart action (fast pulse), vasoconstriction (cutaneous and visceral pallor) and sympathetic overactivity with sweating.

In many discussions on shock or shocklike conditions in animals the cause of shock is attributed to excessive histamine. It has been thought that histamine-like substances liberated from crushed tissue and damaged muscles escaped into the circulation and produced capillary paralysis, loss of plasma and hemoconcentration. This traumatic toxemia theory was given first consideration as a cause of shock by those unaware of Keith's work until Blalock demonstrated that the crushed limbs of animals swelled considerably as the result of local loss of blood and plasma which was quantitatively adequate to account for the fall in blood pressure.

The Clinical Evidence of Hemorrhage. It is important to consider the rate at which hemodilution may occur in normal persons who have been subjected to blood loss Studies on the rate of hemodilution in human volunteers made by Wallace and Sharpey-Schafer showed that, after a loss of 20 to 25 per cent of the blood volume, full hemodilution was not achieved until 32 hours, on the average, had elapsed The hemoglobin reading immediately after an injury may thus be a poor index of the severity of the bleeding

The best evidence pointing to hemorrhage as the most important factor in shock includes the history of the amount of blood lost, the physical examination—for example, gross swelling of the soft tissues in a wounded part can accommodate considerable quantities of blood; and the clinical course. The response to early and adequate transfusion makes it evident that patients in very profound shock may recover completely when the blood volume is restored, provided further hemorrhage can be arrested.

Circulatory collapse due to plasma loss occurs in burns and crushing injuries As a result of tissue trauma in burns and crushing injuries the permeability of the capillaries is altered and a fluid closely resembling plasma passes out into the tissues. The more important sequela of this type of trauma is renal failure, the syndrome which is termed the crush syndrome

In a few patients who have shock from severe injuries the blood pressure on first examination may be found to be raised These patients are pale, and the radial pulse may be of small volume. These patients often subsequently manifest the commoner signs of oligemic collapse with or without evidence of intracranial hypertension

Blood losses up to a liter are well tolerated by normal persons As long as such persons remain recumbent the signs of shock are not clinically obvious, apart from slight acceleration of the pulse and reduction of blood pressure by about 10 mm of mercury The blood pressure seems to be maintained by an increased peripheral resistance During this stage of hemorrhage there is a considerable reduction of the volume of blood in the systemic venous system and also a reduction of the volume of the pulmonary vascular system

Blood donors may faint during the withdrawal of 500 ml of blood. When such a collapse occurs, the fall of blood pressure is accompanied by a slowing of the heart rate. During the faint the right auricular pressure rises and the cardiac output is slightly increased Vasovagal collapse seems, therefore, to be due to a sudden loss of peripheral resistance (see Carotid Sinus, Chapter 5). The condition usually subsides spontaneously in the recumbent position

sex, age, habitus, muscularity or adiposity, activity, state of hydration, and condition of the heart and blood vessels. It is these variations which have limited the use of the values for blood volumes in diagnosis.

All but excessive additions or losses of blood only temporarily affect the blood volume. If a transfusion of blood is given to a normal person, water and electrolytes escape, the extra erythrocytes are forced out of circulation, and within 2 or 3 hours the blood volume returns to normal.

A transfusion of 500 ml. of blood in an adult may increase the erythrocyte count and the hemoglobin as much as 8 to 10 per cent within one day but no more thereafter. The erythrocyte count may be increased by 1,000,000 cells per cubic millimeter if 15 ml. of blood per kilogram of body weight is administered. Transfused leukocytes are almost immediately removed from the circulating blood Diuresis and a visible diminution of edema will follow a blood transfusion if the patient has been edematous and has normal concentration of serum proteins. A fever, if due to the anemia, will subside within one day.

Intravenous infusions of dextrose or saline solutions have only a slight, transient effect on the blood volume, since the water leaves the vascular system almost as fast as it goes in Plasma, albumin, amino acids and acacia have a little more prolonged effect.

It appears that the blood volume, which in health is fixed and regulated at a constant optimal level for the individual, may be changed and maintained at a different level in disease, and attempts to make a quick change in the new abnormal blood volume are resisted by the body. Severe chronic hemorrhage with unrelieved oligemia results in fixation of blood volume at an abnormally low level This condition has been termed chronic shock

Acute losses of blood are followed by immediate entrance of extravascular water into the blood stream This is followed more slowly by the entrance of protein and cells If the blood loss has been large, these compensatory mechanisms are inadequate. In such instances restoration of blood volume depends on transfusions or on the slow natural process of blood regeneration.

Reductions in blood volume are compensated for by. (1) tachycardia and more forceful heart beats; (2) polypnea which aids return of blood to the heart; (3) vasomotor effects which shift blood to the vital centers; (4) increase of plasma by an influx of fluid from the tissues; (5) mobilization of protein and surplus erythrocytes and (6) prevention of anoxia by a rising coefficient of oxygen utilization Severe hemorrhage may cause the blood volume to fall so low that the body is no longer able to adjust to the deficiency.

A *blood volume increased* to an abnormally large amount often is beneficial when it develops slowly as a compensatory response to polycythemia vera, congestive heart failure or free arteriovenous communication A blood volume increased to an abnormally large amount, produced by rapid transfusion of large quantities of blood, may do harm by embarrassing the heart or by producing such secondary effects as hemorrhage, pulmonary edema or renal failure

Changes in blood volume in disease are rarely of diagnostic aid except in shock and perhaps in polycythemia vera

Shock. The term shock is employed to describe many and diverse states, conditions or actions Here the term is employed to designate an acute peripheral circulatory failure due to loss of circulating fluid or derangement of circulatory control brought about by injury.

Any attempt to produce a clinical classification of shock can be only provisional Blalock's classification into hematogenic, cardiogenic, neurogenic and vasogenic forms often is difficult to apply in clinical practice owing to the lack of accurate knowledge of the complex interrelations of the contributing factors in any given case. McMichael's classification of shock includes such varied causes of shock as hemorrhage, vasovagal syncope, pulmonary embolism, bacterial toxemia, diabetic coma and the crises of Addison's disease, it too is difficult of application.

volume, the blood pressure level is the most valuable sign for early diagnosis of clinical traumatic shock in which hemoconcentration does not occur

To summarize, it must be stated that for practical purposes the recognition of shock will have to be based on the presence of a combination of the commonest manifestations and features, as constituting the most adequate means of detection of the presence of shock. The objectivity of blood pressure determinations increases the significance of very low blood pressure readings in the state of shock. In practice it is inevitable that in a certain proportion of cases peripheral collapse will progress unrecognized until a stage of irreversible circulatory deficiency has developed

Reactions from the Transfusion of Blood. A transfusion of blood may be followed by a febrile reaction The fever often is not accompanied by other symptoms. In some instances the temperature may reach 104 to 105 F (40 to 40 5 C) but this lasts only a few hours A chill and subsequent fever may follow within an hour after the transfusion, or may be delayed for 24 hours. These reactions may be due to small thrombi in the transfused blood In some instances there may be excessive alkali or acid in the diluting fluids. The rubber tubing has been held responsible for reactions because it contained soluble toxic substances, or it was not sufficiently cleansed and thus contained bacterial proteins Excessive quantities of blood or parenteral fluids given in the presence of advanced myocardial weakness may be followed by sharp coughs, precordial pain, back pain, dyspnea and cyanosis which indicate right-sided cardiac failure Such a reaction may progress to pulmonary edema and terminate fatally

Allergic reactions characterized by urticaria, swelling, swollen throat and joints, lymph node enlargement, and fever may follow a blood transfusion These may not be related to the volume of blood given A leukocytosis follows transfusions.

Incompatible blood may produce symptoms before much blood has been introduced, and if the transfusion is stopped, often no serious injury results The symptoms are precordial oppression and pain, restlessness, anxiety, flushing of the face, b[illegible] d respiratory rates [illegible] weak pulse, a chill, [illegible] occasionally delirium without evidence of shock Hemoglobinemia, hemoglobinuria, hemorrhagic tendencies, jaundice, oliguria or even anuria may follow. Anuria and uremia may be followed by diuresis and recovery The ultimate prognosis in regard to the kidneys in a given case of hemolytic reaction to transfusion is determined by the degree of tubular damage or the severity of the lower nephron nephrosis.

If the patient is already in shock and incompatible blood is given, immediate symptoms may not be detectable, but a delayed fatal reaction may ensue within a week.

There are substances in both the erythrocytes and the serum of the blood which may cause transfusion reactions

The Blood Groups. The serum of certain persons when mixed with a suspension of red cells from certain other persons causes agglutination of the cells. This phenomenon is attributable to the presence of substances known as iso-agglutinins. Human serum [illegible]

[illegible] whenever an agglutinin and its corresponding receptor are present.

A characteristic of the erythrocytes is the possession of receptors and this factor determines the blood group. This trait is inherited as a dominant mendelian

It seems that when shock is profound (systolic blood pressure lowered to 60 mm of mercury or less), the circulating blood volume has often been reduced to 2 liters or less This opinion is substantiated by the quantities of blood or plasma required to bring the blood pressure back to normal However, chronic reductions of blood volume attained slowly as in a severe anemia are common without vascular hypotension

In severe shock the pulse is rapid, but it is seldom more than 120 per minute, while at other times it is slow (80 per minute) in the presence of a low blood pressure.

Chronic Reduction of Blood Volume. The chronically ill patient with loss of weight and debilitation is more susceptible to shock, less able to tolerate a minimum of hemorrhage, is intolerant of isotonic sodium chloride solution and frequently displays fluid and salt retention after such infusions The weight depletion and the other reactions are not associated with an actual reduction of the potential vascular bed but often are associated with a reduction of plasma proteins and total blood volume For these reasons it has been found that blood volume and the total electrolyte deficits in depleted patients should be calculated on the basis of a standard for the usual weight prior to the illness. If these calculations are made and the electrolytes and plasma proteins are replaced, these patients are less likely to suffer shock after small hemorrhages at the time of surgical operation

Criteria For Recognition of Shock. The common factor in the production of shock is a discrepancy between the effective circulating blood volume and the actual volume capacity of the vascular bed. This discrepancy is primarily responsible for the clinical symptomatology consisting of a low body temperature, feeble and rapid pulse, cold skin, exhaustion and decreased arterial pressure. When these manifestations are present, shock may be profound and therapy may be ineffective. It is therefore desirable to have criteria which will express the earliest, asymptomatic phase of the disparity between blood volume and vascular bed.

The basic disturbance in all types of shock is a *reduced blood volume.* Estimation of the blood volume can be regarded as the most logical index of impending shock The determination of blood volume is feasible in practice by the use of Evans blue dye However, this method would not be adequate for following the progress of shock since estimations cannot be repeated at frequent intervals.

Hemoconcentration may be used for the recognition of shock According to Moon it constitutes the earliest detectable manifestation of shock as well as the most accurate index of its severity Mainly on the basis that absence of hemoconcentration expresses normal capillary permeability, Moon contends that hemorrhage should be differentiated from shock, since hemorrhage is accompanied by hemodilution and only terminally may be associated with hemoconcentration. In contrast to this concept, Blalock has shown that an irreversible typical syndrome of shock with pathologic signs of increased capillary permeability, which is as a rule associated with hemoconcentration, may be elicited by slow removal of blood. Davis also observed identical pathologic features in protracted hemorrhage and in traumatic shock The differentiation between shock and hemorrhage has not been generally made. Harkins summarizes this point of view, stating that a differentiation between hemorrhage and other types of shock would not have any diagnostic, prognostic or therapeutic value In patients often both whole blood and plasma are lost Hence hemoconcentration is not a regular feature and, except in cases of burns, cannot be relied on as an accurate sign for recognition of early clinical shock.

Many clinicians believe, and perhaps rightly so, that the detection of a low or falling arterial pressure constitutes the most reliable early clinical feature of shock The value of blood pressure readings has been emphasized by Evans and his associates, who concluded that, as compared with hemoconcentration and blood

kept at icebox temperature, agglutination may occur (cold agglutination). The clumps break up as soon as the mixtures are warmed Such serum will similarly clump any red cells added to it. This reaction is not specific but has been used empirically in the diagnosis of atypical pneumonia.

Acute hemolytic anemia has been recorded in patients whose blood contained cold agglutinins in high titer. Some have attributed this to intravascular agglutination resulting from chilling of the extremities

Despite all known precautions in obtaining and preparing blood for transfusions, there remain indeterminate individual differences in human blood in addition to those represented by known factors Unfortunately these individual differences cannot always be detected in all instances and transfusion reactions may ensue

Infections From Blood Transfusions. Homologous serum jaundice, infectious hepatitis, malaria and syphilis have been acquired from blood transfusions

REACTIONS TO ADMINISTRATION OF LIVER EXTRACTS

Reactions to liver extract occur in about 1 of every 10 of those who receive it Intramuscular injection of liver may cause local pain, tenderness, fever, and an area of induration at the site of injection.

Reactions to parenteral administration of liver may be observed when preparations of whole (crude) liver are administered These reactions are of two types, immediate and delayed

The symptoms of the immediate reactions from the injection of liver extract commence in from 5 to 30 minutes after injection and consist of nausea, weakness, faintness, and palpitation There may be generalized itching, tingling and flushing of the skin Choking sensations or actual choking and angioneurotic edema, substernal pain, pain in the back and collapse are rare

The symptoms of the delayed reactions are not severe These reactions commence from one day to one week after liver extract is given The manifestations often are itching and flushing of the skin with or without urticaria Chills and fevers, vomiting, and discharges from the nose and eyes are common

Once reactions have appeared, they usually increase in severity with subsequent injections Mild reactions may be controlled by injecting smaller doses, and the immediate symptoms are relieved by injection of 0 5 ml of epinephrine solution (1:1,000)

SUSPENSION STABILITY OF THE BLOOD—THE SEDIMENTATION TEST

Variations in Disease. The erythrocyte sedimentation reaction is a nonspecific reaction which is said to give information concerning the morbid processes within the body The reaction may be accelerated when the temperature, pulse and leukocyte count are normal, particularly in chronic disorders and in localized inflammatory diseases It likewise may not be accelerated when all the foregoing data are abnormal When broadly and liberally interpreted, the sedimentation rate is increased in acute general infections In acute catarrhal inflammation the rate tends to be normal In localized acute suppurations, such as pelvic inflammatory disease, there is often an acceleration In chronic localized infections the rate varies with the extent and nature of the infection The blood sedimentation tends to be accelerated in the presence of malignant tumor which has begun to produce failure of health

The sedimentation reaction is a worthless test for the detection of the presence of a specific occult disease, for so many times it is accelerated in those who are in good health and who remain so for months and years after having had an accelerated sedimentation rate A single accelerated sedimentation is never more than an interesting observation unless it is very high It is the trend toward an increase or a decrease in acceleration of sedimentation of the erythrocytes which is of the greatest clinical value.

character The group characters are often incompletely developed at birth, especially the agglutinins, but become evident after 3 to 12 months. After these have once developed, the group never changes, although the agglutinating activity of the serum may vary or even disappear. Since possession of receptors by the red cells is the factor which determines the blood group, it is preferable to designate the groups by symbols which indicate their receptor content, rather than by arbitrarily chosen numerals The four groups therefore are termed A, B, AB, and O (no receptors)

The Agglutinogens A_1 and A_2. Clear-cut subdivisions of the major blood groups have been demonstrated only in groups A and AB. If the agglutinative activity of properly selected group B or group O sera are titrated with cells from many group A individuals, the latter fall sharply into two subgroups. One subgroup possesses cells which are agglutinable in relatively weak dilutions of serum, whereas the cells of the other are agglutinated only in relatively high concentrations The titer for cells of the first subgroup may be four to eight times that for those of the second subgroup. Landsteiner and associates on the basis of absorption tests and other procedures attribute this and other differences between the subgroups to the possession of different agglutinogens in the cells, they designated the readily agglutinable subgroup as A_1, the other as A_2. Subgroup A_1 is about four to five times as numerous as A_2 Serum from group O and group B usually contains two agglutinins active on A cells, one, known as anti-A or α, agglutinates both A_1 and A_2 cells, about equally, the other, anti-A_1 or α_1, agglutinates only A_1 cells

The Rh Factor In rare instances patients who have received repeated transfusions of blood from donors of the homologous major blood group eventually exhibit severe hemolytic reactions although previous transfusions even from the same donor had caused no reaction It has been shown that these reactions in most cases are due to the development in the recipient of antibodies for an agglutinogen in the cells of the donor which is different from A_1, A_2, B, M, and N To this agglutinogen the term Rh is given because the corresponding anti-Rh agglutinin is identical with one which can be produced in rabbits by injections of blood from rhesus monkeys By use of agglutinating sera from such patients or from immunized animals, the Rh agglutinable factor can be demonstrated in about 85 per cent of (white) persons tested In the 15 per cent who were Rh-negative, normally no anti-Rh agglutinin is demonstrable. It may appear (only) after immunization, either as a result of repeated transfusions of Rh-positive blood, or as a result of pregnancy when the fetus is Rh-positive Immunization occurs, however, in only about 2 to 4 per cent of the cases in which it might be expected.

In a woman so sensitized a first transfusion of Rh-positive blood may cause a hemolytic transfusion reaction Antibodies from the mother may also gain access to the fetal circulation and cause erythroblastosis For such sensitized patients it is imperative to have Rh-negative donors

Blood sera taken from different sensitized individuals may differ qualitatively in their agglutinative action on various Rh-positive cells Three specific types of agglutinating sera have been recognized (1) the standard anti-Rh serum (anti-Rh_0) which agglutinates the red cells of 85 per cent of the individuals tested, (2) a type (anti-Rh') which agglutinates the cells of 70 per cent, and (3) a third (anti-Rh") which agglutinates the cells of only 30 per cent Between 1 and 2 per cent of individuals are Rh-positive, but this is not detected by use of the first type of serum. Certain sera may contain two agglutinins, for example, anti-Rh_0 and anti-Rh', or anti-Rh_0 and anti-Rh"

Minor (Cold) Agglutinins In certain cases the serum of one individual may agglutinate the cells of another belonging to the same blood group, or to group O, even if the action of anti-Rh agglutinins is excluded, provided the mixtures are kept at icebox temperature. These reactions are dependent upon the interaction of several different agglutinin-receptor pairs, only one pair, P_p has been extensively studied These agglutinins are independent of the four blood groups, A, B, AB, and O. They are weak and occur only in high concentrations of serum and rarely cause transfusion reactions When transfusion reactions occur, they are due to errors in group determinations

In rare instances when mixtures of serum and cells from the same individual are

from the megakaryocytes, the multinucleated giant cells of the bone marrow, as pinched-off fragments of the cytoplasm of these cells. Howell (1937) demonstrated that in cats they are formed from megakaryocytes lying in the pulmonary capillaries rather than in the bone marrow. In pathologic conditions, particularly in chronic myelogenous leukemia, occasionally in Hodgkin's disease and pernicious anemia, large masses of cytoplasm may be found in blood films.

In these conditions *megakaryocyte nuclei* occasionally are found in the blood The typical, large lobate nuclei seen in marrow films cannot pass through the pulmonary capillaries, but small nuclei or nuclear fragments may get through. They are two to four times the diameter of an erythrocyte or larger, and round, oval, or irregular in shape

The blood platelets are indispensable for normal blood coagulation Their life is brief, about 3 or 4 days. They are thought to be removed by the spleen and other reticuloendothelial tissues The normal number (150,000 to 250,000 per cubic millimeter of blood) varies with the method used to count them.

Platelets are increased in most conditions associated with active cell formation in the marrow. Among these conditions are (1) many acute infections, (2) after hemorrhage, (3) chronic myelogenous leukemia, (4) polycythemia and (5) Hodgkin's disease

Platelets are diminished in (1) idiopathic purpura haemorrhagica, (2) pernicious anemia, (3) aplastic anemias, (4) acute leukemias (the "primary" thrombopenias), (5) some severe infections, (6) acute or chronic poisoning with benzol, radium, arsphenamine, gold salts, phenylethylhydantoin (mirvanol), sedormid (allyl-isopropyl-acetyl-carbamide), barbiturates (rarely) and other agents and (7) after excessive radiation (secondary thrombopenias)

Coagulation time (Lee and White) is from 5 to 8 minutes The *bleeding time* is usually stated to be 1 to 3 minutes depending on the method employed

The Purpuras. The purpuras are manifested by spontaneous hemorrhage in the skin, mucous membranes, and internal organs

Purpura Haemorrhagica (*Werlhof's Disease*) Purpura haemorrhagica is called also essential, primary, thrombocytopenic or idiopathic purpura These purpuras are due to a decrease or to an absence of blood platelets

The cause of the disease is unknown Purpura haemorrhagica is principally a disease of children and young adults It is uncommon in the aged The disease has been present at birth in full term and premature infants and is known to have been present in both the infant and the mother

A well-pronounced individual familial and racial tendency to the disease is prone to be manifested in early life Members of the white race are more likely to be affected than those of other races There is, however, no clearly defined, sex-linked, inherited trait The disease is commoner in girls and young women than in boys and men. It is uncommon in Negroes

There is an inability of the blood to coagulate and control capillary leakage. The defect in coagulation is apparently due to a decrease of platelets, a thrombopenia

The consensus regarding the *cause of the thrombopenia* is that it is a disease of the bone marrow in which one or all of the following abnormalities are extant a decreased formation of blood platelets or increased destruction of platelets, or increased requirements for them

Symptoms The symptoms usually appear suddenly in a person who has a history of having bruised easily for some time or for a long time The first symptom may be spontaneous epistaxis, especially after acute respiratory infection or heavy cigarette smoking The cutaneous lesions are manifested by a few scattered petechiae or successions of ecchymoses into or beneath the skin These appear most frequently on the extremities, neck and thorax but may appear anywhere They may be extensive and cover a large part of the body. Unless epistaxis and bleeding of the gums have occurred, the patient will not complain of oral lesions.

Excessive bleeding may follow surgical operations such as dental extraction and tonsillectomy, or more frequently may occur after cuts and slight injuries. Subcon-

SOME POPULAR CONCEPTIONS OF THE BLOOD

There is the popular conception that relationships by descent from a common ancestor have been determined by the character of the blood. The terms pure blood, good blood, full blood, and half blood by the same token reflect the implication that blood is the part of an individual which determines the social and the biologic qualities of that individual National and racial differences too are qualified by such terms as German blood, English blood, Negro blood These popular conceptions have no scientific foundations Blood in no way influences the transmission of hereditary characters. The idea that "blood is thicker than water," indicating a blood tie between members of a family or individuals, is completely false. It is now clear that the only blood tie between human beings is the fact that they are members of the species *Homo sapiens*. The hemic traits, like all other traits, are determined by the presence or absence of certain genes in combination with one another The blood has no causative influence on the combination of genes It is subject to the influence of gene combinations the same as all other tissues. Thus there are inherited normalities and abnormalities of the various constituents of the blood the same as there are of the other tissues of the body.

COAGULATION OF BLOOD AND HEMORRHAGIC DISORDERS

In this section are included those hemorrhagic disorders of the blood which are due to faulty coagulation or to the increased capillary permeability

The active ingredients necessary for the formation of a blood clot are derived from (1) the blood plasma, (2) the blood platelets and (3) the aqueous tissue extracts

The *blood plasma* contains prothrombin, calcium, thromboplastin, fibrinogen and heparin The prothrombin is formed in the liver, and on coagulation of blood is converted to thrombin by the action of thromboplastin with calcium acting as a catalyst. Thromboplastin is abundant in the blood platelets as well as in the plasma and tissue extracts The thromboplastic activity of tissue extracts is derived in part from or accounted for by the presence of cephalin. Just how thromboplastin converts prothrombin to thrombin is not known

Fibrinogen present in the plasma is converted to fibrin by the action of thrombin The fibrin is the basis of the clot. A blood clot without platelets remains soft, with platelets it becomes firm and retracts

The presence of heparin seems to prevent the blood from coagulating within the circulatory system.

Aberrations in the presence and functions of the forementioned substances in the blood are the basic causes for failures of the blood to clot

The failure to form the proper blood clot is the cause for many hemorrhagic disorders In some hemorrhagic disorders the lack of a particular substance, such as prothrombin in liver disease, can be determined In many others the actual origin of the hemorrhagic disease is not wholly determinable. Other causes of hemorrhagic disorders are aberrations in the erythrocytes and infections of the erythrocytes as in malaria and *Bartonella bacilliformis*

The etiology, the manifestations and the classification of the diseases affecting the blood-clotting constituents of the blood may be confusing In an attempt to clarify somewhat the confusion, Fowler has separated these so-called hemorrhagic states into three types. (1) There is a failure of the clot to retract and become firm owing to a lack of platelets (2) In some instances the elements of the blood may be normal, and there is present weakness or an increased permeability of the capillary walls. It seems too that in some instances there may be a combination of these features in the same patient (3) In some there is a failure of the clot to form owing to a deficiency of one or more of the substances concerned in normal clot formation.

The *blood platelets*, or *thrombocytes*, are round or oval bodies, usually 2 to 3 microns in diameter, although they vary greatly in size and shape. In films they show a marked tendency to form clumps They contain no nuclei They are believed to arise

for recovery after successful splenectomy are better than 1 out of 2. Hemorrhage into various parts of the nervous system is the commonest serious complication. However, recovery has been observed after intracranial hemorrhage.

Symptomatic Purpura. The symptomatic purpuras are associated with a diagnosable disease or a poison. Recovery from the causative disease or the poison ameliorates the purpura. These purpuras are due to capillary fragility

In any *infection* which causes a high fever, such as septicemias, typhoid fever, subacute bacterial endocarditis, miliary tuberculosis, rickettsial fevers, smallpox, vaccinia, scarlet fever, and measles, purpura often occurs

Physical agents, chemical, vegetable, and *animal products,* of diverse origins cause purpura and thrombopenia without affecting the erythrocytes or leukocytes except for the losses incurred from hemorrhage. Thrombopenia may develop and purpura may be associated with burns, sunburn and sunstroke

The *organic arsenicals,* some hypnotics, and sulfonamides may induce purpura The development of purpura in an adult should arouse suspicion of a drug as the etiologic agent

Many *vegetable foods* may cause purpura Of the vegetable cosmetics, orris root may be mentioned as being of etiologic importance.

The important *animal products* as causative agents are various immune sera and the venoms from snakes and insects

Purpura, thrombopenia, prolonged bleeding time, nonretractility of the clot and positive results of the tourniquet test are manifestations of a purpura originating in the hematopoietic system In the acute leukemias immature leukocytes are present In the acute, subacute and chronic forms of this disease there are fever, a cachectic state, ulceration in the mouth, glandular and sometimes hepatic enlargement. In the aplastic anemias thrombopenic purpura is accompanied by leukopenia, relative lymphocytosis and few or no signs of erythrocyte regeneration Myelophthisic anemia may be accompanied by purpura Extensive metastasis may be present for some time before roentgenograms of the bones will reveal the presence of the causative lesions.

In Banti's syndrome, Gaucher's disease, Felty's syndrome and hemolytic jaundice the great size of the spleen, as well as other objective findings, is often sufficient to distinguish these conditions from purpura haemorrhagica

The diagnosis of the symptomatic or secondary purpuras can be made only when there is present a well-defined capillary weakness manifested by positive tourniquet reactions There is no well-defined abnormality of the blood These same diagnostic criteria apply in purpura simplex, purpura senilis, purpura cachetica, orthostatic purpura, allergic purpura and vitamin deficiency purpura

In thrombocytopenia the platelets are reduced, the bleeding time prolonged, the coagulation time slightly delayed, clot is nonretractile, the tourniquet reaction uncertain, and there may be changes in the leukocytes

Allergic Purpura. Allergic purpura is known also as Schonlein-Henoch purpura, peliosis rheumatica, anaphylactoid purpura and hemorrhagic capillary toxicosis

Nonthrombopenic purpuras occur in association with symptoms of allergy, for instance, edema, erythema and urticaria The purpuras which are classified as of allergic origin are Henoch's purpura, Schonlein's purpura and the purpura associated with erythema simplex, erythema multiforme, erythema bullosum, erythema vesiculosum, erythema nodosum, and urticaria pigmentosa (see Chapter 18).

The predisposition for allergic purpura is the inheritance of the allergic state. The exciting cause may be bacteria or bacterial products (vaccine) or an article of food. In some instances a hypersensitivity to cold or to heat or to sunshine may be the cause for purpura

A mild edema may be present on the face, in the hands or feet, or about the knees and elbows, and this may be the only complaint An allergic purpura may

junctival or retinal hemorrhage or hemorrhage into the tongue may be present Hemorrhagic bullae and hematomas frequently are complained of in severe instances of the disease.

Bleeding from the urinary and genital organs is frequent. Uterine bleeding may be often expressed by profuseness and duration of the menstrual period and may be the only symptom of the disease. Purpura haemorrhagica may commence at puberty or even before, and may then be manifested by vaginal bleeding or menorrhagia. Hematuria is a common symptom which may originate in any part of the urinary tract from the renal pelvis downward.

Melena or, less frequently, hematemesis indicates bleeding in the upper part of the gastrointestinal tract Rectal bleeding is less common than bleeding from the upper part of the alimentary tract. Hemorrhage into solid viscera does not occur in this disorder

Intracranial hemorrhages are often multiple and vary in size from petechiae to large extravasations of blood producing in some cases pachymeningitis or hemorrhagic encephalitis Intracranial hypertension is not produced by this disorder. The brain, the spinal cord, and the cerebrospinal meninges are all equally affected

Examination. *The patient's skin may be normal in appearance with an occasional petechia or areas or splotches of ecchymosis, or it may be covered with* petechiae and ecchymoses The lesions are deep red, purple, brown or yellow, depending on their age. In a third of the cases the spleen is palpable but not greatly enlarged The physical findings depend on the extent and site of the bleeding. Rarely is there shock If there be intracranial bleeding, the most frequent signs are those of hemiplegia or meningitis

The application of a tourniquet or a blood pressure cuff to the arm is followed by the appearance of numerous petechiae (a positive reaction to the tourniquet test)

The blood *platelets* are greatly decreased in number, and they vary in size; giant forms, minute platelets and deeply stained ones are reported The platelets may be absent There is some correlation between the platelet count and the severity of bleeding In acute exacerbations of the disease bleeding usually does not occur *unless the platelets are fewer than 50,000 per cubic millimeter* of blood. In chronic disease the platelet count may remain less than this without hemorrhages

The bleeding time is prolonged and a failure of the blood clot to retract is confirmatory evidence of the thrombopenia. The coagulation time of the blood is within the normal limits

The anemia in acute purpura is normocytic and proportional to the extent of blood loss Immediately after a severe hemorrhage, there may be macrocytic anemia. When the bleeding has been severe and long continued, the anemia may *become* hypochromic and microcytic in type.

The leukocyte counts in acute purpuras reveal normal numbers In chronic purpuras there may be a relative lymphocytosis

Diagnosis. The platelet count is reduced, the bleeding time is prolonged, the clot is nonretractile, and the coagulation time is essentially normal Anemia may be present; if so, it is proportional to the blood loss There is a positive tourniquet reaction There may be morphologic platelet changes. The diagnosis *of purpura* haemorrhagica is made after toxic causes for thrombopenia are known to be absent

In the differential diagnosis the pre [illegible] and changes in structure and size of the lymphocytes is [illegible] of purpura haemorrhagica The nonthrombopeni[illegible] om purpura haemorrhagica by the family history and by manifestations of allergy.

In all proved instances *of acute purpura haemorrhagica, even* after many relapses, recovery usually takes place. However, there are chronic instances of the disease from which the chances for recovery are fewer than 1 out of 3 The chances

which there were spontaneous ecchymoses in 88 members, is similar to the form described by Giffen.

The diagnostic criteria for purpura simplex are the presence of mild purpuric skin manifestations unassociated with definite abnormalities in the blood The tourniquet test is positive. Rheumatoid arthritis and rheumatic fever are frequently associated

Pseudohemophilia (Hereditary Hemorrhagic Thrombasthenia, Thrombasthenia Purpura). Pseudohemophilia belongs to the group of hereditary hemorrhagic diatheses. It is a hereditary disease with no predilection for sex. The disease has been considered to be due to a *congenital capillary dysplasia* Others have considered the condition to be due to thrombasthenia, the platelets, however, are normal. The disease may begin in infancy or at any time thereafter.

The clinical symptoms are similar to those of hemophilia There are recurrent nosebleed, hemoptysis, hematemesis, vaginal bleeding, hematuria and hemarthrosis. The bleeding may follow slight trauma and may be mild or severe and in some instances fatal

On examination there often is neither anemia nor splenomegaly The blood cells and platelets are normal The bleeding time is prolonged but the coagulation time is normal. Thus the changes in the bleeding and coagulation time are the opposite from those present in hemophilia The tourniquet test is positive.

In diagnosis, the genealogic history signifies that the bleeding tendency is transmitted by both sexes The bleeding time is prolonged, but there are normal numbers of platelets and coagulation time is normal A family history of epistaxis may be accepted as evidence of the hereditary nature of the disorder.

Hemophilia. In hemophilia there is a permanent inborn defect which inhibits blood coagulation This defect is hereditary in origin and is sex-linked It is a recessive mendelian trait.

The disease is limited to the male but is transmitted from the male through an unaffected daughter to her son. The sons of an affected man cannot transmit the defect to any of their descendants Only the daughters are capable of transmitting the trait Females never manifest the disease

Long inheritance through females, with the males being insufficiently affected to manifest the disease, is an acceptable explanation of the occurrence of *sporadic cases* of hemophilia.

It has been well demonstrated that there is no lack of fibrinogen, no calcium deficiency, no reduction in number of platelets The defect seems to be present in the plasma Plasma thromboplastin is absent or reduced in hemophilic plasma. The globulin fraction of the plasma proteins contains the so-called antihemophilic globulin or the globulin substance which is effective in shortening the coagulation time of the blood from the hemophiliac

SYMPTOMS The symptoms begin in infancy or childhood and are manifested by *habitual hemorrhage* which occurs spontaneously or from trauma There is a prolonged oozing of blood from cuts or wounds Hemorrhage from the lips, mouth, nose, gums, and tongue, or resulting from slight trauma or from the eruption and loss of teeth, takes place. Hemorrhage into the brain or spinal cord may result in transient or permanent paralysis and sensory disturbances. Hematuria from bleeding in the bladder or the kidneys may give rise to ureteral clots which produce severe colic

Hemorrhage into the joints as the result of the hemophilic process produces the hemarthrosis characteristic of the disease. The onset of the joint hemorrhage is sudden The joint is flexed, swollen, warm and painful Discoloration of the skin occurs only about small joints. The process is chronic and its symptomatology resembles that of a chronic infectious process. The ankle is frequently the joint earliest

begin and remain as a purpuric spot without swelling, but more often the lesions are multiple and accompanied by swelling Blebs may form which have the appearance of herpes with a hyperemic base or there may be bullae or even pemphigoid lesions Interspersed between lesions or associated with the purpura may be a *diffuse erythema*, with or without swelling.

The diagnostic features are the same as those for a nonthrombocytopenic purpura. There often is a leukocytosis with an eosinophilia. Identification of an allergin assures the correctness of the diagnosis.

Schönlein-Henoch Disease (*Nonthrombopenic Purpura*). Allergic purpura associated with gastrointestinal symptoms in children and adolescents is *Henoch's* purpura. *Schönlein's* purpura affects the periarticular structures of the joints of young adults.

In Henoch's purpura there is urticarial serohemorrhagic effusion into the intestinal wall In Schonlein's purpura there is a periarticular effusion into the joint which is not hemorrhagic

In Schonlein's disease the joints, often the knees, form periarticular effusions and there are pains in the limbs. There are purpuric spots over the legs. The joint manifestations and the hemorrhagic manifestations are commoner in the lower extremities than in the upper extremities.

SYMPTOMS The abdominal symptoms of Henoch's purpura may develop before any purpuric eruptions appear. Usually there is colic which varies from mild and transient to severe The pain is not localized, and occurs in all parts of the abdomen Vomiting, diarrhea or constipation, and tenesmus may occur. In some patients constipation may be so stubborn as to suggest intestinal obstruction In rare instances the purpuric gut may form intussusception Rheumatoid pains and fever may precede the attacks of abdominal pain and purpura.

In either or both of these purpuras involvement of the *nervous system* and *organs of special sense* may be revealed by the development of transient paresis and epileptiform convulsions The eyes may be affected by hemorrhages into the eyelids, conjunctivae or retinas Optic atrophy, iritis and ophthalmitis are the usual ocular involvements

Hematuria from renal involvement is rare.

EXAMINATION. General abdominal tenderness without rebound is present. The purpura may or may not be present on the first examination When it does occur, it is commoner over the lower extremities

The joints, particularly a knee, may be swollen, and purpuric spots may be present over the legs

Hemorrhage is rarely sufficiently marked to produce anemia. There may be neutrophilic leukocytosis, sometimes eosinophilia The blood platelets are not significantly affected, and bleeding time, coagulation time, and clot retraction are normal Results of the tourniquet test and the snake venom test may be positive or negative

The *urine* may be normal, or blood or albumin may be found. Examination of the stools may reveal blood

DIAGNOSIS Henoch's purpura is diagnosed when there are visceral manifestations; Schonlein's purpura, when there are joint manifestations. Before purpura or other skin manifestations have appeared, a diagnosis of either disease cannot be made. If purpura is present, the normal blood findings exclude thrombopenic purpura. The platelets are not reduced. Coagulation time and bleeding time and clot retraction are normal. The tourniquet reaction may or may not be positive

Purpura Simplex. Purpura simplex may be a hereditary disease or it may be acquired It is purpura without hematologic changes

Hereditary familial purpura simplex, as described by Davis in 27 families in

which there were spontaneous ecchymoses in 88 members, is similar to the form described by Giffen.

The diagnostic criteria for purpura simplex are the presence of mild purpuric skin manifestations unassociated with definite abnormalities in the blood. The tourniquet test is positive. Rheumatoid arthritis and rheumatic fever are frequently associated

Pseudohemophilia (Hereditary Hemorrhagic Thrombasthenia, Thrombasthenia Purpura). Pseudohemophilia belongs to the group of hereditary hemorrhagic diatheses. It is a hereditary disease with no predilection for sex. The disease has been considered to be due to a *congenital capillary dysplasia.* Others have considered the condition to be due to thrombasthenia, the platelets, however, are normal The disease may begin in infancy or at any time thereafter.

The clinical symptoms are similar to those of hemophilia There are recurrent nosebleed, hemoptysis, hematemesis, vaginal bleeding, hematuria and hemarthrosis The bleeding may follow slight trauma and may be mild or severe and in some instances fatal

On examination there often is neither anemia nor splenomegaly The blood cells and platelets are normal. The bleeding time is prolonged but the coagulation time is normal Thus the changes in the bleeding and coagulation time are the opposite from those present in hemophilia. The tourniquet test is positive

In diagnosis, the genealogic history signifies that the bleeding tendency is transmitted by both sexes The bleeding time is prolonged, but there are normal numbers of platelets and coagulation time is normal A family history of epistaxis may be accepted as evidence of the hereditary nature of the disorder.

Hemophilia. In hemophilia there is a permanent inborn defect which inhibits blood coagulation This defect is hereditary in origin and is sex-linked It is a recessive mendelian trait.

The disease is limited to the male but is transmitted from the male through an unaffected daughter to her son. The sons of an affected man cannot transmit the defect to any of their descendants. Only the daughters are capable of transmitting the trait Females never manifest the disease.

Long inheritance through females, with the males being insufficiently affected to manifest the disease, is an acceptable explanation of the occurrence of *sporadic cases* of hemophilia.

It has been well demonstrated that there is no lack of fibrinogen, no calcium deficiency, no reduction in number of platelets. The defect seems to be present in [illegible]

of the blood from the hemophiliac.

Symptoms The symptoms begin in infancy or childhood and are manifested by *habitual hemorrhage* which occurs spontaneously or from trauma There is a prolonged oozing of blood from cuts or wounds Hemorrhage from the lips, mouth, nose, gums, and tongue, or resulting from slight trauma or from the eruption and loss of teeth, takes place Hemorrhage into the brain or spinal cord may result in transient or permanent paralysis and sensory disturbances. Hematuria from bleeding in the bladder or the kidneys may give rise to ureteral clots which produce severe colic

Hemorrhage into the joints as the result of the hemophilic process produces the hemarthrosis characteristic of the disease The onset of the joint hemorrhage is sudden. The joint is flexed, swollen, warm and painful. Discoloration of the skin occurs only about small joints The process is chronic and its symptomatology resembles that of a chronic infectious process The ankle is frequently the joint earliest

involved. The knee is often permanently crippled. No joint can be said to be exempt from involvement by hemophilia

EXAMINATION. Mentally these patients are normal, often precocious. There is no enlargement of lymph nodes and the spleen is not palpable.

On examination of the site of the origin of hemorrhage the tissue is hard, indurated, raised and purplish black The hemorrhage at the site of origin may be entirely absorbed while the margin is still progressing to involve large areas of the body

Hematomas may involve areas in which the pressure may lead to gangrene. If sufficient pressure is exerted on a nerve, contracture may result (Volkmann's contracture)

Examination of the joints during the acute attacks reveals that the joints are swollen, tender and painful on active or passive motion. If the disease in a joint has been present for a few weeks and the swelling and tenderness are still present, the condition is beginning to be chronic. If acute attacks of hemarthroses are repeated from time to time, there is a permanently swollen joint with local deformity, contractures and muscular atrophy. Repeated hemorrhages in a large joint in time tend to cause less immediate increase in the size of the joint as the articular capsule becomes thickened and restricts swelling As chronicity progresses, the larger joints contain fibrous contractures and bony ankylosis. In the smaller articulations complete destruction of the joints takes place Atrophy and proliferation of bone and roughening of the articular surfaces with lipping and formation of osteophytes and cysts retard or stop growth

Other than the prolonged coagulation time, there is nothing characteristic in the blood

DIAGNOSIS. The task of making the diagnosis begins with the finding of a prolonged coagulation time if there is no history of repeated bleeding and familial occurrence A deep hematoma may resemble, on examination, a suppurative condition, a sarcoma, tuberculosis, arthritis deformans, Perthes' disease, or a syphilitic affection of the bone or joint Bleeding from the alimentary tract, despite the fact that the coagulation time of the blood is known, requires a differentiation from all those conditions known to produce such hemorrhages.

In the hereditary hemorrhagic diathesis, the bleeding time is prolonged Those who have familial epistaxis (pseudohemophilia) possess normal bleeding and coagulation times.

The diagnosis of hemophilia is based on the following findings present in a male. (1) prolonged coagulation time of the blood and of recalcified oxalated plasma, (2) normal clot retraction time after the clot has once formed, (3) normal bleeding time except at times of active hemorrhage when it is prolonged and (4) normal numbers of platelets, normal prothrombin time and variable degrees of anemia The tourniquet reaction is negative

In hemophilia death in time inevitably ensues from exsanguination However, some of these patients may live for years.

Anticoagulants as a Cause of Hemorrhage. Hemorrhage from anticoagulant therapy usually ensues (1) in persons taking dicumarol without medical supervision (or it may occur in patients receiving heparin therapy), (2) from poor laboratory control, (3) from overdosage by the physician, (4) from ill-advised surgical procedures and (5) from diagnostic errors, which account for the anticoagulant-induced hemorrhages and fatalities Ill-advised surgical procedures and diagnostic errors are not considered here.

The incidence of hemorrhage following the use of anticoagulants is increased if the dosage is pushed to the limit in the belief that it is more desirable to assure patients full protection against thrombo-embolic complications and thus run some

risk of hemorrhage, than to use a dose carrying with it so little chance of hemorrhage that it might fail to inhibit intravascular clotting.

An editorial in the Journal of the American Medical Association in 1950 revealed that data obtained from a questionnaire answered by 136 physicians experienced in the use of dicumarol and heparin indicate that major hemorrhage occurred in 2 per cent of about 15,500 patients treated The chief site of major hemorrhage was the urinary tract Gross hematuria occurred in 93 cases recorded in the questionnaire, but in no instance was it the cause of death although hematuria was associated with fatal bleeding in other sites in 3 cases Hematuria was not followed by residual renal impairment Most other instances of major bleeding were associated with pathologic lesions in the gastrointestinal tract or lungs or were in postoperative sites

In the "Report of the Committee for the Evaluation of Anticoagulants in the Treatment of Coronary Thrombosis With Myocardial Infarction" hemorrhagic complications occurred in 54 patients, or 9 per cent of the treated group; in half of them the condition was mildly severe An additional 6 per cent of the treated group had hemorrhage not due to anticoagulants, while in the control untreated group hemorrhage occurred in 6 per cent Hemopericardium was found in 11 of the treated and only 4 of the control group.

Bleeding induced by dicumarol is usually controlled by adequate amounts of water-soluble vitamin K or menadione bisulfite Transfusions of blood and plasma are of value after hemorrhage due to either heparin or dicumarol

Clinicians experienced in the use of anticoagulants agree there is less risk of hemorrhage with heparin than with dicumarol The Lee-White test of clotting time to control heparin therapy can be done by the average technician. Protamine sulfate, given intravenously, helps to correct the coagulation defect following heparinization Unless the available laboratory is well versed in the pitfalls of the prothrombin determination, dicumarol should not be used

The vagaries of the Quick test of prothrombin time necessitate special knowledge of the technic. False confidence may be inspired if the laboratory records the prothrombin time in percentage of normal To follow adequately the prothrombin response the normal range of the test as done by the available laboratory should be known and the dicumarol dosage should be adjusted in an attempt to maintain the prothrombin time between two and two-and-a-half times the average normal, expressed in seconds, obtained by identical technic with the same thromboplastin, in which event the percentage of prothrombin activity will fall between 10 and 30 per cent, a safe yet effective bracket Hemorrhage rarely occurs until the prothrombin activity is depressed to 5 per cent unless some pathologic lesion is present in the kidneys, gastrointestinal tract, lungs or brain

THE LYMPH NODES AND THE SPLEEN

In association with the regional diseases of the neck the usual causes for enlargement and disease of the lymph nodes were considered In that discussion it was mentioned that enlargement of the lymph nodes is commonly caused by infections opportunely situated Enlargement of spleen, lymph nodes, and occasionally the liver may result from infections which are blood borne but more commonly is due to causes other than infection

In the present discussion interest is in enlargement of the lymph nodes, the spleen and occasionally the liver in association with or as a manifestation of blood dyscrasias or primary disease of the lymphatic tissues

Malignant Lymphoma. Many generic terms are used to designate diseases of the lymphatic system characterized by progressive tumor-like enlargement of lymphoid tissue with eventual fatality, and histologically by multiplication of one or more of the elements normally present in lymph nodes to the point of destruction of the nodal architecture. The term malignant lymphoma is in general use and has the advantage of being noncommittal in regard to the cause for the enlargement.

In recognition of the complexity of the problem of nomenclature of malignant lymphomas the American Association of Pathologists and Bacteriologists established the "Registry of Lymphatic Tumors" and in 1934 set the seal of the registry's

approval on the schematization and terminology employed. The arrangement of data represented an attempted fusion of three classifications: (1) cytologic, based on morphologic recognition of component proliferating cells, (2) gross anatomic, depending on the distribution of the process throughout the organs of the body and (3) clinical, contingent on physical signs and hematologic manifestations

Hardly was the printer's ink dry on this classification before Gall and Mallory offered a somewhat different classification, because attempts to apply the registry's terminology convinced them that it is not practical for routine use. They presented a cytologic classification of malignant lymphomas and showed its advantages in a clinicopathologic survey They demonstrated by multiple examinations at significant time intervals that the cytologic type is remarkably constant, although a few cases show *a progressive failure of differentiation as the disease progresses. In* contrast, in a classification based largely on distribution, such features as the presence or absence of leukemia, generalization versus localization, and "sarcomatous" growth were considered important These have been shown to be inconstant and changeable, thereby requiring variation in classification from time to time in order to fit the stage of the disease The vast majority of Gall and Mallory's 618 cases from which histologic material was available could be readily divided into seven categories: (1) stem cell lymphoma, (2) clasmatocytic lymphoma, (3) lymphoblastic lymphoma, (4) lymphocytic lymphoma, (5) Hodgkin's lymphoma, (6) Hodgkin's sarcoma and (7) follicular lymphoma.

This classification differs from accepted classifications primarily in the subdivision into two types of what has generally been grouped under the heading reticulum cell sarcoma, one type in which the cells are highly undifferentiated and resemble lymphoid stem cells, for which the authors have proposed the name stem cell lymphoma, and a *second type in which the cells show recognizable features of differentiation in the direc*tion of tissue phagocytes, which they have termed clasmatocytic lymphoma It has also proved useful to divide the tumors showing clear evidence of belonging to the lymphocyte series of cells into lymphoblastic and lymphocytic types depending on whether the immature or the mature cells predominate. Hodgkin's disease too has appeared divisible into lymphomatous and sarcomatous types. Follicular lymphoma has been shown to be a form of malignant lymphoma and not, as has been claimed, merely an inflammatory process

The etiology of none of the malignant lymphomas is known, but the majority must now be regarded as neoplasms. Some investigators have considered Hodgkin's disease to be of an infectious origin; thus the terms lymphogranuloma, lymphogranulomatosis, lymphomatosis granulomatosa The malignant nature of Hodgkin's disease is indicated by the terms lymphosarcoma, reticulum cell sarcoma, giant follicular hyperplasia, round cell sarcoma, leukosarcoma, lymphadenosarcoma, lymphocytoma, monocytoma and pseudoleukemia

Often all of these diseases will be, as is done here, included under one heading The three general all-inclusive headings which may be employed are (1) malignant lymphoma, (2) lymphoblastoma and (3) lymphomatoid diseases

The clinical manifestations of these conditions are so nearly identical in some and so varied in others as to make differentiation on clinical findings impossible Differentiation can be made, but not always agreed on, by pathologists by histologic study Two general groups can be distinguished, namely, the reticulum cell sarcoma or the lymphosarcoma, and Hodgkin's sarcoma. These are histologic diagnoses; the use of terms designating cytologic diagnoses is avoided until biopsy has been made and the results have been recorded.

Lymphosarcoma and Hodgkin's Disease. By some observers Hodgkin's disease is divided into three types: (1) *Hodgkin's granuloma* is the common type of the disease The manifestations of the granuloma are protean and the condition is usually fatal within a few years (2) *Hodgkin's paragranuloma* is a comparatively benign condition beginning in almost all instances in the lymph nodes of the neck [illegible] nodes (see [illegible] as a (3)

comparatively localized tumor, develops rapidly, and results in death. These three types of Hodgkin's disease have in common the presence of Sternberg-Reed cells, and any one type of the disease may be transformed into another type.

From the standpoint of morphologic change in lymph nodes, there is no sharp distinction between leukemia and the forms of Hodgkin's disease

Hodgkin's disease has been regarded as a type of malignant disease different from most of the other cancerous processes Many of its characteristics suggest an inflammatory origin. The possible infectious characteristics of Hodgkin's disease have been reexamined by the previously unused technic of serial passage of the Hodgkin's disease lymph-node extracts in embryonated chicken eggs A slight lethal effect in the embryos ensues The amniotic fluid collected after numerous serial passages from Hodgkin's disease-inoculated embryos has certain filtrable, transferable, and virus-like properties.

Hodgkin's disease affects a younger age group than do the other lymph-node disorders The average ages vary from 36 to 50 years In all forms of the disease men are more frequently affected than women.

SYMPTOMS The various diseases chiefly affecting lymph nodes produce similar symptoms A lymph-node enlargement is the usual complaint

The general symptoms of Hodgkin's disease are widely varied and, for instance, may resemble those of tuberculosis or undulant fever. Tachycardia may be observed which is out of proportion to the degree of fever and thus may be remindful of thyrotoxicosis

The absence of general symptoms early in the course of lymphosarcoma is in contrast to Hodgkin's disease in which, in the common granulomatous type, constitutional symptoms appear early. In children Hodgkin's disease is prone to be characterized by a prolonged period of fever. The fever may be moderate, irregular and continuous In adults too a fever may last weeks or months with afebrile periods of variable duration In a few patients the temperature ranges to 104 F (40 C) or higher In about 1 of every 16 there is irregular, remittent, or continuous pyrexia of several days' to several weeks' duration interrupted by periods of remission. This pyrexia is termed Pel-Ebstein fever or alternating pyrexia

The intensity of the pruritus, often with little or no objective cutaneous manifestations, is maddening, and the suffering from this symptom may be indescribable.

Bone symptoms and anemia are varied and consist of pain and weakness.

Urogenital symptoms are present in about one third of cases. These symptoms result from invasion or from pressure The urinary symptoms are hematuria, pyuria, retention of urine, pain in the back, a mass in the flank, or symptoms indicative of disease of the prostate gland or of the testicles

Paresthesias and pain are common complaints which have a neurologic origin

EXAMINATION The intensity of the pruritus in an occasional case of Hodgkin's disease is evidenced by scratch marks and obvious irritation of the skin A brownish, localized or generalized pigmentation of the skin may accompany pruritus or appear independently of it In Hodgkin's disease, erythema, a macular morbilliform eruption, herpes zoster, eczema, papules, wheals, vesicles, bullae, furuncles, and lichenification occur Ulceration may follow necrosis of lymph nodes or cutaneous tumors

Firm intracutaneous nodules, colorless or shiny bluish red, are the commonest specific lesions in lymphosarcoma However, similar lesions may be present in Hodgkin's disease.

Involvement of superficial nodes is present in almost all those who have one of these lymph-node disorders In rare instances of Hodgkin's disease, however, no involvement of lymph nodes has been found at necropsy.

The nodes of the neck are usually the first affected in Hodgkin's disease and in the "sarcoma" group. In Hodgkin's disease primary mediastinal and abdominal adenopathy may be found. The lymph-node enlargement is along the sternocleidomastoid muscles and in the supraclavicular spaces, often forming a large, irregular, nodular, collar-shaped tumor over the anterior lower portion of the neck

The common lymph-node involvement of the neck, nasopharynx and tonsils was discussed in Chapters 4 and 5. Hodgkin's disease and other lymph-node tumors which invade the mediastinum and lungs were described in Chapter 9. May it be repeated here that chylous effusion is much commoner in the diseases chiefly affecting lymph nodes than as the result of any other cause, and of these it is most frequent in follicular lymphoma.

In follicular lymphoma (Mallory) gastrointestinal involvement is rare but may occur. Ascites is frequent and is often chylous in this disease In Hodgkin's disease the gastrointestinal tract is rarely affected, but it may be exclusively involved The digestive symptoms may be due to enlargement of lymph nodes or may arise from the systemic febrile effects of the disease (Pel-Ebstein).

Digestive symptoms are due to the presence of enlarged lymph nodes or are the result of systemic effects in the late stages of these lymph-node diseases. Gastric lymphosarcoma occurs and is a rare malignant gastric tumor. The average age incidence of gastric sarcoma of the Hodgkin type is lower than that of gastric carcinoma The symptoms are similar to those of carcinoma or peptic ulcer.

The liver and spleen may not be enlarged Those seriously ill of the disease, however, often have splenic enlargement

In the intestines the frequency of occurrence decreases distally, except that the rectum is involved more often than the colon The lesions may be polypoid, protruding into the lumen of the intestine, annular, or diffuse, and infiltrating the wall of the bowel

Bone lesions are often demonstrated by roentgenograms in Hodgkin's disease, lymphosarcoma, and rarely in monocytoma The lesions are found most frequently in the pelvis, vertebrae, ribs and femora, but other bones may be involved In most cases more than one bone is affected

Paresthesias and pain are the commonest neurologic findings Herpes zoster is often the cause of the pain Diplegia as the result of circulatory disturbances of the spinal cord, or due to collapse of involved vertebrae producing angulation and compression of the cord, is unusual Pathologic fractures rarely occur

There are no *blood changes* in these disorders which can be considered as diagnostic of Hodgkin's disease

The value of bone marrow study in the diseases which chiefly affect lymph nodes is to exclude leukemia (the aleukemic form)

The basal metabolic rate is frequently increased. The uric acid content of the blood may be considerably increased The alkaline serum phosphatase, if persistently elevated, may indicate bone invasion

In Hodgkin's disease the erythrocyte sedimentation rate may be accelerated or may be normal

Diagnosis The diagnosis of all of the diseases affecting the lymph nodes is established by biopsy of an enlarged node

The problem of diagnosis is much more difficult when the primary lesion does not affect one of the superficial groups of lymph nodes, for then the symptoms may attract attention to any of the systems of the body and may mimic any one of a great many diseases Thus there may be chronic dermatitis The cutaneous manifestations may be accounted for only on histologic study of the skin There may be a tumor of the bowel; the onset may be characterized by *melena or hematemesis* or ascites The symptoms may suggest pulmonary tuberculosis, bronchogenic carcinoma, septicemia, endocarditis, typhoid fever, rheumatic fever, pyelitis, prostatic disease or some neurologic disorder

The factors which determine the course of the illness in individual cases are

amination of the blood. This condition is often termed pseudoleukemia, aleukemic leukemia or small cell lymphosarcoma Clinically the manifestations are the same as those of Hodgkin's disease Histologic study is required for diagnosis.

Reticuloendothelial Granulomatosis. The reticuloendothelial system contains cells with endothelial and reticular attributes and showing a common phagocytic behavior. These cells are distributed in the spleen, lymph nodes, liver (Kupffer's cells), bone marrow and the clasmatocytes. Reticuloendothelial cells are concerned with blood cell formation, the storage of fatty materials, phagocytic destruction of blood cells and the metabolism of iron and pigment

Well informed pathologists and clinicians may regard what may seem to be, from the standpoint of the clinician, a form of lymphosarcoma or a Hodgkin's disease as reticuloendothelial granulomatosis Two diseases named after men who first described them may be given as examples. Hand-Schüller-Christian disease and Letterer-Siwe disease

Hand-Schüller-Christian disease is a systemic reticuloendothelial granuloma of unknown origin The disease may exist in a widely disseminated form characterized by reticuloendothelial granulomas in many parts of the body, or it may be a more limited granulomatosis occurring, for instance, in the ribs, skull or other bones and the lungs. The individual granulomas present may fail to exhibit the characteristics of foam cells and cholesterol crystals Usually, however, there are large foam cells present. The nonlipid granulomas usually involve the bone marrow, lymph nodes and spleen The replacement of the blood-forming marrow tissue with the granulomas is responsible for the anemia (see Myelophthisic Anemia, page 843) which is often the most conspicuous manifestation In some instances of so-called Letterer-Siwe disease the spleen, the lymph nodes and the vertebral marrow are entirely free of granulomas

The phagocytic properties possessed by the reticuloendothelial cells are manifested by the tendency to contain quantities of hemosiderin pigment obtained from nearby hemorrhages present in the lymph nodes, bone marrow or spleen

There is a progressive enlargement of the granulomas, lymph nodes and often the spleen With the onset of necrosis in the lesion the cholesterol is liberated from the cells and it may be absorbed into the blood stream and give rise to transient hypercholesteremia However, the value for serum cholesterol is usually normal

Letterer-Siwe disease is a form of xanthomatosis characterized by great hypertrophy of the macrophages in the spleen, bones and lymph nodes These cells are devoid of lipoid substances.

THE SPLEEN

On examination of the abdomen the spleen may be found to be enlarged without any recognizable accompanying symptoms At this point it is well to enumerate at least some of the causes for splenic enlargement Some are common causes and others are uncommon, and probably this listing is not complete

CAUSES OF SPLENOMEGALY

1. Infectious·
   a Acute fever, septicemias, pyemias, formation of abscess with splenic abscess, bacterial endocarditis and disseminated lupus erythematosus
   b Chronic syphilis and tuberculosis
   c Parasitic infections malaria, leishmaniasis, trypanosomiasis, schistosomiasis and echinococciasis
   d Infectious mononucleosis
2 Circulatory (often mechanical)·
   a. Cirrhosis of liver, Banti's disease, thrombosis of either the portal or splenic veins as a complication of cirrhosis or any other circulatory cause of thrombosis
   b. Congestive splenomegaly—heart failure

3. Hemic and lymphatic.
   a Chronic hemolytic anemias.
   b Chronic anemia with or without blood destruction.
   c Purpura haemorrhagica.
   d. Benign lymphatic hyperplasia.
   e. Malignant hyperplasia. leukemias.
   f. Polycythemia vera

4. Metabolic
   a Gaucher's disease
   b. Niemann-Pick disease
   c Schuller-Christian disease.
   d. Amyloidosis.
   e Diabetic lipemia, hyperthyroidism

5. Tumors
   a Cysts dermoid and pseudocysts.
   b Benign tumors: hemangioma, lymphangioma, fibroma.
   c. Follicular lymphoma, monocytoma, reticulum cell sarcoma, Hodgkin's lymphoblastic and lymphocytic lymphoma
   d Primary and metastatic malignant lesions.
   e Boeck's sarcoid

Banti's Disease (Congestive Splenomegaly) At this place it is wel sider the disease variously known as *Banti's disease, splenic anemia, an* congestive splenomegaly

The disease may come on in childhood Females were twice as num males in Banti's series and this was true of Giffin's series but has not been in all reports. A familial incidence is rare but is not unknown

Congestive splenomegaly and the accompanying changes of Banti's synd now considered to develop as a result of any pathologic process. congenital matory, neoplastic, parasitic or fibrotic, which interferes with the flow of por through the liver or at any point in the splenic or portal vein In the majority the obstruction is only partial and has developed gradually Thrombophlebi *splenic or portal veins, portal cirrhosis, and cirrhosis due to schistosomiasis are* monest causes of obstruction Obstruction in the mesenteric veins leads to f of varicosities and to intestinal bleeding, but unless the portal or splenic veins involved by extension, the obstruction will not produce congestive splenomega

The spleen is enlarged The capsule is thickened, and adhesions between th and the stomach or diaphragm may be present On section the spleen is gra and firm The trabeculae are prominent and malpighian bodies are inconspicu

The hemorrhagic tendency is due both to local and to systemic causes affec portal system. The walls of the veins of the portal system are stretched and particularly those of the distal portion of the esophagus and sometimes thos rectum The mucosa overlying the distended veins is thinned and eventually a process which contributes to the erosion of the wall of the underlying vein

The thrombopenia and hypoprothrombinemia present in this syndrome de *prompt formation of effective blood clots at points where small ruptures of t* have occurred

SYMPTOMS. The onset is usually insidious and there may be only a s heaviness or fullness in the upper part of the abdomen In some instances th may come with suddenness, when vomiting of blood or the passage of larg stools takes place *in a patient who is otherwise in good health* In other in abdominal pain or discomfort, or symptoms of weakness and a general la referable to anemia bring the patient to the physician Flatulence, diarrhea, indigestion, or even mild jaundice in association with abdominal pain and may appear. Epistaxis occurs in about a third of the cases, but other hemo ... such as purpura are *unusual*.

EXAMINATION. A brown pigmentation of the skin may be present. The spleen is large and may extend to the pelvis Moderate hepatic enlargement has been observed at an early stage in perhaps a third of the cases. Lymphadenopathy is absent.

Endoscopic examination is attended with small risk in the experienced hands. This examination helps to identify the varicosities and to determine their approximate size when they are situated in either the esophagus or rectum.

Roentgenographic study of the esophagus when filled with barium may reveal varices in that situation

Splenomegaly may precede anemia which, unless hemorrhages have occurred, is moderate and, as a rule, normocytic. Repeated hemorrhages result in hypochromic microcytic anemia. Subsequent to a hemorrhage the reticulocytes may be slightly or moderately increased in number, and occasional normoblasts may be observed A macrocytic anemia may appear temporarily following an acute hemorrhage

Leukopenia is constant except after hemorrhages. Leukocyte counts less than 5,000 per cubic millimeter have been observed in about two thirds of the cases The diminution of the leukocytes often affects all the types of cells, the ratio of the polymorphonuclear leukocytes to the lymphocytes and monocytes remaining normal.

The platelet count is often somewhat reduced, and sometimes it is well below 100,000 per cubic millimeter

Sternal puncture reveals varied conditions in the bone marrow In the earliest stages of the syndrome, the bone marrow is hyperplastic, especially the erythropoietic series If there is thrombopenia, it may be difficult to differentiate the syndrome from idiopathic thrombopenic purpura In the later stages, when there are ascites and severe impairment of hepatic function, the bone marrow may be hypoplastic.

DIAGNOSIS A diagnosis of Banti's disease depends on elimination of hemolytic jaundice, aleukemic leukemia, and bleeding from peptic ulcer The presence of lymphadenopathy or of immature leukocytes in the blood smear favors conditions other than Banti's disease. The presence of decreased hepatic functional activity favors Banti's disease The diagnosis of the disease is made more nearly certain by the presence of esophageal varices. Persistent leukopenia and thrombopenia, with little or no alteration after hemorrhage are characteristic manifestations of Banti's syndrome

The disease may run a prolonged and often benign course and may appear to be spontaneously arrested, the patient living for a number of years without disability. At any time, however, the uneventful course may be interrupted by one or more episodes of gastrointestinal hemorrhage, portomesenteric venous thrombosis or hepatitis In other instances there is steady progression with the development of symptoms of hepatic insufficiency and the signs of portal venous obstruction and death. In some instances death follows a hemorrhage or some other complication

Rupture of the Spleen. Rupture of the spleen may occur from nonpenetrating trauma Such a rupture may cause primary or delayed hemorrhage It is suggested that changes in the hematoma, whether subcapsular or perisplenic, may be a factor in delayed hemorrhage and may account for the majority of ruptures occurring on the sixth or seventh day after trauma

It is important to attempt to obtain a history of trauma in every case of sudden pain in the upper left quadrant of the abdomen running occasionally to the left shoulder. The injury may have been slight or have occurred a week or more previously and to the patient it may seem too insignificant to be mentioned

The difficulty in making an early diagnosis is one of the most important causes of the high mortality rate from rupture of the spleen The syndrome of delayed hemorrhage is most difficult to detect The hemorrhage is delayed in about 20 per cent of the cases, with a latent period on the average of about 6 days from the time of injury to the onset of a massive hemorrhage. Cases with latent periods as long as

6 months have been reported. Roentgenologic diagnostic signs and abdominal paracentesis may aid in establishing the diagnosis of injury of the spleen in cases of delayed hemorrhage.

LEUKOCYTES

In the blood there are: (1) mature neutrophilic leukocytes, which have segmented or filamented structures, (2) immature neutrophilic leukocytes without filamented or segmented structures, (3) eosinophils, (4) basophils, (5) lymphocytes and (6) monocytes

In normal blood the *total leukocyte count* ranges from 5,000 to 10,000 per cubic millimeter Variations in number as great as this may be observed in the blood of the same normal individual from day to day, and wide daily variations may occur.

The leukocytes are made up of three distinct groups of cells which differ from one another fundamentally in origin, in structure, and in function: the granular (myeloid) leukocytes or granulocytes, the lymphocytes, and the monocytes

The *granulocytes or myeloid* cells contain definite granules which are visible in fresh as well as in stained preparations. In normal blood there are three varieties, distinguished by the staining reaction of the granules: neutrophils, eosinophils (acidophils), and basophils

Immature granulocytes, the ancestors of the aforesaid types of cells, may appear in the blood in certain pathologic conditions. Normally some mechanism prevents the passage of cells into the blood before they are mature It is the phenomenon of their entrance into the blood stream, and not the character of the cells themselves, which is pathologic The presence of the pathologic process, however, is manifested by the presence of these immature cells in the blood stream In general, the more numerous and *the less mature these cells are, the more serious is the disturbance of the hematopoietic tissue*

Lymphocytes or *lymphoid cells* arise from the fixed lymphatic tissues In the normal circulating blood two types of lymphocytes are differentiated, namely, large and small lymphocytes The small lymphocytes comprise 20 to 30 per cent of the leukocytes in the peripheral circulation

Immature lymphocytes, like the immature granulocytes, in the presence of certain diseases may pass into the circulating blood The more immature *the lymphoid cell is,* the more serious is the disease causing the immature cells to appear in the circulating blood

Plasma cells are present in small numbers in the bone marrow but rarely are they observed in the peripheral circulation The exact origin of these cells is unknown

Turk's irritation leukocytes may be observed in the circulating blood if there be an irritating lesion of the bone marrow or a disease of the lymphoid tissues.

The consensus is that *monocytes* are a separate series of cells They arise *from reticular* cells of the reticuloendothelial tissues In a mature form they comprise 4 to 5 per cent of the cells of the circulating blood.

Leukocytosis. The term leukocytosis signifies an increase in the total leukocyte count (more than 10,000 per cubic millimeter of blood) In most instances leukocytosis is due to an increase in the neutrophils, and thus the term neutrophilic leukocytosis may be employed if the neutrophils predominate. A leukocytosis is called relative if the total leukocyte count is within normal limits, but the percentage of neutrophils is increased to more than 70 per cent of the total count. The term absolute leukocytosis is employed if the total number, as well as the relative number, is increased The terms relative leukocytosis and absolute leukocytosis are of little value in diagnosis except when there is an absolute leukocytosis

OCCURRENCE. Normal persons may show a neutrophilic leukocytosis (1) after muscular activity (sometimes marked) and convulsions and (2) after *cold baths* or exposure to cold. There may be (3) leukocytosis in infants during the first few

days and (4) slight leukocytosis in pregnancy during the last few weeks and in the puerperium (sometimes marked, up to 20,000)

Neutrophilic leukocytosis occurs in most acute infections, particularly acute pyogenic infections The leukocyte count in acute pyogenic infection usually ranges around 15,000 per cubic millimeter; in lobar pneumonia it may reach 30,000 to 40,000

In many instances of acute poisoning, such as by heavy metals, and by drugs such as acetanilid and digitalis, the counts may reach 20,000 per cubic millimeter. In acute gout, in diabetic acidosis and in uremia leukocytosis may be present A leukocytosis follows acute hemorrhage and acute hemolysis of erythrocytes, surgical operations, coronary thrombosis, pulmonary infarction, and burns. The greatest increases in the leukocyte counts are observed in the leukemoid reactions and in the leukemias

SIGNIFICANCE Leukocytosis occurs when there is an increased demand for leukocytes The degree and type of response vary greatly and often unaccountably. In interpreting the leukocytic counts, changes in the differential count and qualitative alterations in the leukocytes are more significant than an increase in their total number Particularly, more reliable information is obtained by a study of the neutrophils from the standpoint of their maturity An increased demand is met by the production of new cells by the bone marrow When leukocytes are hastily liberated from the bone marrow many of the cells are carried into the circulation before development is completed

Arneth measured the phenomenon of immaturity of leukocytes by accepting the degree of segmentation of the nucleus as a criterion of maturity In making differential counts he divided the neutrophils into five groups The first group included all cells with unsegmented nuclei, and the second to the fifth groups (inclusive) comprised cells with nuclei composed of two to five lobes respectively. In instances of active infection the relative number of cells containing one or two nuclei was increased, and as these happened to be recorded on the left hand side of his tally sheets, this change was termed a *shift to the left* The term a shift to the left is frequently employed by hematologists to indicate an increase in the cells with unsegmented nuclei or a decrease in the number of cells with segmented nuclei Arneth regarded the shift to the left as far more significant than a rise in the total leukocyte count Arneth's method of counting is no longer employed in the laboratory The method now used varies with the individual hematologist, but often it is some modification of the method of Schilling

In general, in a severe infection there is an increased total leukocyte count with a high percentage of neutrophils, or there may be a complete failure to develop a leukocytosis, so that a leukopenia is present The immature cells outnumber the mature cells, eosinophils are absent, lymphocytes are reduced in number, and many cells show toxic-degenerative changes in the nucleus or cytoplasm The most valuable diagnostic and prognostic information is gained from repeated counts and studies of the cells to determine the directional trends in the forementioned changes in the leukocytes A single examination is often inconclusive and may be misleading.

Eosinophilia. The eosinophils normally comprise 2 to 4 per cent of the leukocytes They decrease in numbers during an acute infection but may return in increased numbers during the convalescence The term eosinophilia designates increases of more than 8 or 10 per cent Eosinophilia occurs chiefly (1) in *infection with animal parasites,* (2) in extensive *skin diseases* of any type; (3) in *allergic reactions,* (4) in chronic myelogenous leukemia and occasionally in Hodgkin's disease, (5) with certain tumors of the ovary, and in Cushing's syndrome, (6) in focal lesions of the bone marrow, and after splenectomy, (7) *in pernicious anemia* after liver therapy Irregular response of eosinophils occurs in adrenocortical insufficiency (see Addison's Disease, Chapter 14).

Eosinophilia in Tropical Disease. Lowe and his colleagues have expressed the belief that in malaria and in the helminth infections two different factors are con-

cerned with the production of eosinophilia: (1) a nonspecific factor similar to *that present in bacterial infections and* (2) *a specific factor* due to helminth infection.

Basophilia. The basophils normally comprise 0 5 to 1 per cent of the leukocytes. A basophilic leukocytosis occurs commonly in chronic myeloid leukemia. In other conditions it is infrequent and of no known diagnostic significance.

Lymphocytosis. The lymphocytes comprise 25 to 35 per cent of the total leukocyte count. *The majority of the lymphocytes in normal blood are the small variety.*

A *relative lymphocytosis* occurs in most of the conditions which show a leukopenia

An *absolute lymphocytosis* occurs in certain infections for instance, in whooping cough, and in tuberculosis of mild or moderately active degree running a favorable course. It *occurs less regularly in certain viral or viral-like infections such as* German measles, mumps, infectious mononucleosis and acute infectious lymphocytosis Lymphocytosis occurs during convalescence from any acute infection, after exposure to ultraviolet radiations, and in lymphatic leukemia. The regular occur*rence of lymphocytosis following acute infections may well be related to the devel*opment of immunity.

The lymphocytes, specifically, produce antibodies. By chemical fractionation of human plasma a large proportion of the antibodies is found to reside in the alpha, beta, and gamma globulins. The gamma globulin is present in the human lymphocyte.

Acute infectious lymphocytosis is a clinical entity characterized by a benign relative and absolute increase in the number of mature lymphocytes.

Smith has summarized the data for the establishment of acute lymphocytosis as a specific entity and differentiated it from infectious mononucleosis, acute lymphatic leukemia and miscellaneous infections associated with a lymphocytosis

In most of the reported instances of the disease the patients had been children, until Duncan reported 2 instances in which the patients were young adults

In most cases the disease is uncomplicated and has a uniformly favorable outcome The clinical manifestations are usually mild or absent. There is neither lymphadenopathy nor splenomegaly, and in all instances the heterophil antibody reaction is negative. The maximal leukocyte counts which have been observed range from 45,000 to 50,000 per cubic millimeter of blood with *85 to 90 per cent* lymphocytes. The lymphocytosis may persist for a period of approximately 3 to 5 weeks.

Monocytosis. Under normal conditions monocytes comprise from 5 to 10 per cent of the leukocytes

Monocytosis may occur in malaria and other [illegible] and is of less regular occurrence in certain viral and rickettsial [illegible] sis may be present in Hodgkin's disease, Banti's [illegible] thane, and monocytic leukemia

A slight increase in monocytes occurs frequently at the height of many acute infections.

Infectious Mononucleosis. This disease is known also as glandular fever, acute benign lymphoblastosis, acute lymphadenosis, monocytic angina and lymphocytic angina.

Infectious mononucleosis is an acute disease characterized by irregular fever, sore throat, often cervical lymphadenopathy, and enlargement of the spleen, and lymphocytosis with abnormal though mature lymphocytes The blood serum contains antibodies against sheep erythrocytes in high concentrations

The disease is cosmopolitan in distribution It appears sporadically and epidemically. The cause is unknown. It seems to be a specific infection. Those who have the disease are known to respond to other infections with the usual polymorphonuclear reaction Cocci, bacilli, viruses, spirochetes and protozoa all have been suspected as *etiologic*

agents but none has been proved. The disease has been thought to be a "lymphatic form" of influenza

The epidemic form occurs in the spring in children and young adults Boys and men are somewhat more susceptible than girls and women. It has been observed that epidemics of influenza in adults may be associated with outbreaks of infectious mononucleosis in children There is no seasonal incidence of sporadic cases. The contagiousness of the disease, if there be such, is low

The incubation period is uncertain, but the best evidence suggests that it is about 11 days

SYMPTOMS. The onset is characterized by fever and aching legs and back Anorexia is commonly present.

Sore throat if present may precede, accompany or follow the onset The throat may be diffusely reddened and a membrane may form Vincent's infection is a common complication. The gums often become tender, swollen and ulcerated and may bleed Epistaxis, hematuria, and rectal bleeding may occur

The temperature may reach 103 to 104 F (39 4 to 40 C), but often the fever is transient and slight A second rise of temperature may occur after an initial drop to normal. Synchronously with this second fever, lymph nodes in the neck are swollen and the throat is sore The fever may be intermittent. The pulse may be relatively slow A certain amount of toxemia is common In some cases the toxemia is severe and prostration supervenes Headache with the fever is often severe.

In some who have this disease there is a continuous feeling of fatigue associated with no abnormal physical findings

The course and duration of the disease are variable The irregular fever usually persists for 1 to 3 weeks, and symptoms disappear in 2 to 4 weeks but may continue longer. Recrudescences are common Adenopathy, splenomegaly and the characteristic blood findings may persist for months, even for years There is often a long period of slight but definite debility following an attack of infectious mononucleosis

Jaundice may develop in from 5 to 14 days after the onset of symptoms and may be the presenting symptom Hepatitis without jaundice occurs Nausea, vomiting, diarrhea and abdominal pain are fairly common symptoms, with or without jaundice. In children convulsions, stupor and coma may occur at the onset.

EXAMINATION Cutaneous eruptions may be present on the face, trunk and arms and may appear from the fourth to the tenth day in a few who have high fever with the disease The lesions are described as pink or pinkish brown, macular or maculopapular lesions 2 to 5 mm in diameter which may fade on pressure, as well as petechiae and hemorrhagic rashes Erythema nodosum and urticaria are described for this disease

An enlargement of the lymph nodes often develops rapidly Commonly the nodes posterior to the sternocleidomastoid muscles and epitrochlear nodes are affected The nodes are discrete, firm and elastic in consistency and are slightly tender They vary in size from ⅖ to 1⅗ inches (about 1 to 4 cm.) in diameter. Axillary and inguinal lymph nodes are usually not enlarged Thoracic or mediastinal lymph nodes may be found on roentgenologic examination to have increased in size, and pressure symptoms may be present

The spleen is palpable in more than one half of those who have the disease. The liver is less frequently palpable Petechial hemorrhages and purpura may be observed in the skin and mucous membranes.

From involvement of the central nervous system the heart rate may be slow, the neck stiff, and a positive Romberg sign and plantar extension may be present Examination sometimes reveals partial ocular motor paralysis, facial paralysis, cutaneous hyperesthesia and signs of diffuse involvement of the lower motor neurons

The characteristic finding in the blood is an increase in mononuclear cells consisting of small lymphocytes, monocytes and large mononuclear leukocytes which

are not normally observed in the blood The increase in numbers of these cells often occurs at the expense of the neutrophils.

The total leukocyte count is usually 10,000 to 15,000 per cubic millimeter but it may be normal or even lower than normal. In half of the cases there is leukopenia during the first week of the disease

The finding of anemia makes the diagnosis of infectious mononucleosis highly improbable. The platelet count is usually normal but thrombocytopenia has been observed. The bleeding time may be prolonged without relation to the platelet count.

When there is jaundice, the van den Bergh reaction is positive, delayed or direct biphasic and bilirubin is as high as 8 to 10 mg. per 100 ml.

Reaction to the serologic tests for syphilis may become transiently positive in a number of cases, and occasionally this may persist for several months. This effect is independent of the presence of sheep cell antibodies, for the positive reaction can be demonstrated in equally high titer even when the sheep cell antibodies have been absorbed out A falsely positive Widal reaction and significant increases of agglutinins for a variety of organisms have also been observed

Albumin and erythrocytes may be found in the urine A gross hematuria may be present Renal function is unimpaired.

The cerebrospinal fluid pressure may be moderately increased. Usually only a few or no cells are present in the fluid, but in a few instances pleocytosis has occurred, with as many as several hundred cells, mostly lymphocytes, present. The sugar content is normal, the protein may be increased and the reaction to the Pandy test may be strongly positive

The serum in those who have infectious mononucleosis contains agglutinins against sheep erythrocytes in high titer, a finding which has proved to be very useful in diagnosis (heterophil antibodies) The heterophil sheep cell agglutinin test often helps to confirm the diagnosis While sheep cell agglutinins are present in normal human serums, especially in patients undergoing serum therapy or suffering from serum sickness, when the antibody titer is higher than 1 64, it is said to be strong evidence of the presence of infectious mononucleosis Gardner and Paul in an analysis of the records of 86 cases studied in the New Haven Hospital found that reaction to this test had been positive in only 60 per cent of the cases, even at the height of the disease. The absence of the heterophil reaction, in some, may be explained by the fact that the sheep cell agglutinins reach a peak rapidly during the first week of the disease and may decrease just as rapidly in some instances

Sternal puncture is of value chiefly to reveal no findings characteristic of leukemia

Diagnosis. In all other blood disorders reaction to the heterophil antibody (Paul-Bunnell) test is negative In leukemia the titer of heterophil antibodies is particularly low The Paul-B[illegible]

The physical findings may [illegible]
be made in the absence of [illegible]
phenomena and immature leukocytes Moderate or severe anemia is almost always present when acute leukemia is first discovered

The greater age of the patients, the history of ingestion of drugs, and the absence of lymphadenopathy or splenomegaly are valuable differentiating features in agranulocytosis.

Infectious Mononucleosis and Benign Lymphocytic Meningitis. It seems that the clinical symptoms, course and prognosis of benign lymphocytic meningitis and of the neurologic manifestations of infectious mononucleosis are indistinguishable. The changes in the cerebrospinal fluid are identical in the two conditions In infectious mononucleosis with neurologic manifestations the enlargement of lymph nodes is usually slight This feature, together with mononucleosis and heterophil agglutinins, may develop only after the neurologic symptoms have subsided or may precede the nervous stage With the presence of such neurologic symptoms, infec-

tious mononucleosis can be excluded only by repeated attempts to demonstrate heterophil antibodies in the blood.

Infectious Mononucleosis and Polyneuritis (*Guillain-Barré Syndrome*). Polyneuritis of the Guillain-Barré type with facial diplegia, extensive peripheral neuropathy and albuminocytologic dissociation of the cerebrospinal fluid may be associated with infectious mononucleosis The neurologic manifestations are those of polyneuritis and the so-called Guillain-Barré syndrome, as evidenced by the multiple involvement of peripheral nerves and an ascending type of paralysis, with spinal fluid which contains a high protein content and no cells.

Leukemoid Reactions. The term leukemoid reaction is applied to a leukemia-like reaction of the leukocytes as a result of an infection or other stimulus. Such a reaction may be granulocytic, lymphocytic, or monocytic depending on the type of cell involved The reaction may be manifested by an exceptionally high total leukocyte count with the appearance of a few or many immature cells or by a great many immature cells without a great increase in the total leukocyte count A leukemoid reaction is commoner in children than in adults and is more frequently due to an infection than to other forms of marrow stimulation.

Leukopenia. A reduction in the leukocyte count to less than 5,000 per cubic millimeter of blood must be mainly at the expense of the neutrophils. It occurs regularly in typhoid fever, measles, influenza, dengue, kala-azar, malaria, the initial stages of smallpox, and extensive glandular tuberculosis It may occur in overwhelming infections, malignant neutropenia (agranulocytic angina), and in primary splenic neutropenia. Leukopenia occurs in acute or chronic poisoning from benzol, acetanilid, the sulfonamides, aminopyrine, lead, mercury, arsenic, thiouracil, dinitrophenol, and occasionally from barbiturates. It occurs after excessive radiation, in idiopathic aplastic anemia, leukemia, and in pernicious and myelophthisic anemias.

A leukopenia of 3,000 to 5,000 per cubic millimeter is commonly observed in apparently normal individuals The differential count may be normal, or there may be a slight relative lymphocytosis

Agranulocytosis. Agranulocytosis is known also as agranulocytic angina, granulocytopenia, granulopenia, agranulosis, agranulocythemia, hypogranulocytosis and idiopathic, malignant or pernicious leukopenia

In the infections known to be associated with leukopenia, granulocytopenia of the degree seen in agranulocytosis is rare The most important known cause is drugs.

The drugs which may produce granulocytopenia are benzene, organic arsenicals, gold salts and coal-tar products (see Diseases Due to Chemical Agents, Chapter 19) *The effect on the blood may be a selective one producing only granulocytopenia.* However, the granulocytopenia is often accompanied by a thrombocytopenia and an anemia These changes in the blood are not usually observed after one or two doses except in large doses of some of the organic chemicals The drugs usually have been administered over long periods of time before causing agranulocytosis

It is evident from daily observation that only a small proportion of persons consuming drugs suffer any ill effects

the blood generally appears only after a relatively large amount has been taken for a relatively long period Thus even after full dosage of one of the sulfonamide compounds, acute agranulocytosis has not developed before one week and usually not before two weeks of treatment Exceptions to this rule, in which leukopenia has developed within 24 hours after the ingestion of the usual therapeutic dose, are rare

Watkins encountered 17 cases in which a *barbiturate* (amytal, phenobarbital, luminal) appeared to be the cause of agranulocytosis

The use of *thiouracil* for the treatment of hyperthyroidism has added to the list of agents producing granulocytopenia.

The drugs which may produce agranulocytosis often cause other manifestations of idiosyncrasy, such as rash, urticaria, edema and asthma The fever, chills, headache and dizziness which have been noted in sensitive persons after administration of the drug suggest an allergic process

SYMPTOMS. The first symptoms are often malaise, fever and perhaps a chill Then follows a period of freedom from symptoms except for fatigue and prostration, and during this time the leukocyte count falls and the granulocytes disappear Several days or longer may pass after these premonitory symptoms and then there is a sudden severe chill and high fever with postrigor prostration.

In those who have a milder degree of the affection, the disease is a less fulminating one When the disease is chronic and recurrent, there may be vague symptoms such as headache, malaise, dizziness and exhaustion, and in some an actual prostration. There may be painful deglutition and generalized pains. In a few who have agranulocytosis the course is characterized by fever, pain over the splenic region, and splenic enlargement. The splenomegaly may be slight to moderate In the less severe instances there may be no symptoms

EXAMINATION. There is a general pallor though the mucous membranes are of normal color or cyanotic. Dermatitis and cutaneous rashes are common. Jaundice without enlargement of the liver is often present. A cervical adenopathy is common Gangrenous ulceration may be found on the gums, tonsils, soft palate, lips, pharynx or buccal mucous membranes, and in the nose, vagina, uterus, anus and rectum Splenomegaly and bone tenderness are usually observed The fever is high, the pulse rapid and weak, and death may ensue in from 3 to 9 days

In allergic agranulocytosis not only the granulocytes but also all other types of leukocytes are reduced in number In fulminating cases the leukocyte count may be less than 2,000 per cubic millimeter of blood and frequently it is less than 1,000

The majority of the cells are lymphocytes In some cases monocytes may be increased relatively and in absolute numbers. In chronic or recurrent types the leukocyte count is rarely less than 2,000 cells per cubic millimeter and the granulocytopenia is less pronounced Usually there is no anemia or thrombocytopenia The sedimentation rate, however, is greatly accelerated

The bone marrow shows normal erythropoietic tissues and normal numbers of megakaryocytes but no granulocytes Plasma cells, lymphocytes and reticulum cells may be increased in number

DIAGNOSIS The diagnosis is based on the presence of the agranulocytopenia The various types of pharyngitis and other infections occurring in the mouth or throat are accompanied by leukocytosis.

Sulfonamides and penicillin have improved the prognosis in this condition by control of the infection until the bone marrow can recover The mortality rate may be more than 50 per cent

Death may occur as the result of hemorrhage following necrosis of mucous membranes or from other causes, even after hematologic improvement seems assured.

Improvement is made certain by the reappearance of leukocytes of the granular series in the blood

Leukemia. Figuratively speaking, leukemia is a malignancy involving one of the series of leukocytes of the blood. There are both acute and chronic forms of leukemia. The acute and the chronic forms are subdivided by the hematologist according to the predominating type of leukocyte and by the clinician according to the rapidity of the progress of the disease. Myelogenous (myeloid) and lymphogenous (lymphatic, lymphoid) forms are distinguished Myeloid leukemia may be referred to as myelogenous, myelocytic, or histiocytic.

Eosinophilic leukemia, polymorphonuclear (neutrophilic) leukemia and basophilic leukemia are names applied to those rare instances in which these cells predominate Monocytic and megakaryocytic leukemias are so diagnosed by the hematologists.

Aleukemic leukemia is the common term used in referring to cases of leukemia in which there is no leukocytosis By some this condition is termed subleukemia

Chronic myelocytic leukemia seems to be commoner in younger persons than the chronic lymphocytic form which is more liable to occur in aging men

Chloroma, derived from the color of the tissue-forming tumors, designates tumors which may occur in the leukemic state. The term may be applied to the disease also.

The etiology is not known Leukemia has occurred frequently enough in several members of a family to give credence to the belief that often there is a hereditary etiologic factor, especially in the lymphocytic form

Congenital myelogenous leukemia is recorded Leukemia occurs oftener in the first 5 years of life than in other periods and here too it is frequently the acute myelogenous form. The disease is commoner in males than in females

An analysis, by Cooke, of the sex and age incidence in 1,500 cases of acute leukemia in children showed the following trends (1) During childhood there is a gradual increase in the proportion of males over females who have acute leukemia, the predominance of boys being greater in later childhood than during infancy. In the first year of life the disease was observed in girls oftener than in boys (2) The age incidence follows a regular curve, which rises from a moderate elevation in the first two years of life to a peak of highest incidence in the third and fourth years, with a sharp decline in the next 3 years and a more gradual progressive fall throughout the latter half of childhood Cooke concluded that acute infections form one of the factors in the production of the disease and therefore play an important part in its causation, since (1) the highest incidence in acute leukemia occurs in early childhood, (2) the type of its age incidence curve tends to follow the frequency of acute infections in children and (3) some acute infection frequently precedes the development of acute leukemia.

After the age of 50 years chronic lymphocytic leukemia is more frequently encountered than the myelogenous types of the disease After the first year of life, the disease is commoner in males than in females

In summary, the etiologic factors present in leukemia, whether they are extrinsic intrinsic or genetic are of unknown origin These [illegible]

cell growth and maturity, much as cancer cells grow.

The *clinical manifestations* of leukemia appear in acute and in chronic stages The disease does not originate in an acute form which progresses to the chronic stages The chronic forms are dissimilar in cellular morphology and are often insidious in onset However, a chronic leukemia will manifest an acute exacerbation of cellular growth and symptoms.

Acute Leukemia. The first symptom of acute leukemia is often the rapid development of weakness and pallor There may be bleeding from the mucous membranes, petechiae and ecchymoses in the skin, sore throat, cough, dyspnea, and generalized pains The pains may be limited to the abdomen The fever, headache, and prostration may be as great as those of some severe infections

A generalized pallor of the skin is characteristically present Often in acute leukemia there is an absence of lymph-node enlargement. In other instances of the disease cervical lymph-node enlargement is great. Generalized adenopathy is more frequently present in lymphoblastic leukemia than in myelogenous leukemia

Purpuric manifestations are characteristically present on the mucous membranes in the nose and the oral cavity. Partially clotted blood may be found at the gingival margins of the teeth, and the gums themselves may be swollen and purplish, the

swelling is sometimes so great that the gums may be pushed over the teeth. Slight trauma on the swollen gums often will leave a hemorrhagic area. Purpuric manifestations, blisters and ecchymosis may be present over any of the areas of glabrous skin.

Splenomegaly is not demonstrable in all cases of acute myelogenous leukemia. However, there is always some enlargement of the spleen in this disease. Splenomegaly may be absent in acute lymphatic leukemia.

Infiltration may occur in the larynx causing hoarseness A mediastinal mass may be the first sign of acute leukemia Effusion into the pleural cavities may be present as a late manifestation

Leukemic nodules have been found in the rectum, appendix, and cecum. The liver often is enlarged The rectal nodules may appear as hemorrhagic polyps and result in profuse rectal bleeding

There may be hematuria, pain and, often, priapism which is exquisitely painful and resists all forms of treatment

Hemorrhage may be present in the conjunctivae, eyelids and other parts of the eyes Exophthalmos is characteristic of chloroma Hemorrhages in the oculi fundi are variable in size and consist of pale centers with red borders Deafness may occur as the result of hemorrhage into or infiltration of the labyrinth or the auditory nerve.

Cranial nerve palsies affecting the oculomotor, facial, and trigeminal nerves, and hemiplegia and other forms of paralysis, convulsions, and findings suggesting encephalitis, meningitis, and transverse myelitis may be present There may be failure of vision, deafness and anosmia from injury from hemorrhages affecting the optic, auditory and olfactory nerves

Anemia and thrombocytopenia of some degree are present in every case of acute leukemia. The anemia is usually normocytic.

Thrombocytopenia is characteristic of acute leukemia Bleeding time is prolonged, clot retraction is poor and the result of the tourniquet test is positive

The leukocyte count is rarely high and may be normal or subnormal It may be as low as 400 per cubic millimeter of blood Persistent leukopenia, together with anemia and thrombocytopenia, often is found to be leukemia The number of leukocytes then suddenly rises to counts as high as 100,000 per cubic millimeter.

There is a distinct predominance of immature leukocytes not usually found in the circulating blood It is by the predominating type of leukocytes that acute leukemia is recognized during life When there is leukopenia, it is these immature cells which are predominant in the bone marrow and which increase in number as the leukocyte count rises

In *acute myeloblastic leukemia* the immature leukocytes possess the characteristics of myeloblasts and undifferentiated myelocytes The presence of immature cells which possess a few granules suggests that the associated cells devoid of granules are of the myeloid series The granules can often be demonstrated in peroxidase stains

The presence of many myelocytes or a large spleen and the lack of hemorrhagic phenomena and thrombocytopenia suggest the chronic form of the disease.

In *acute lymphoblastic leukemia*, the predominant cells (lymphoblasts) make up about one half of the total number of cells The remainder of the cells are recognizable lymphocytes, some of which contain a few azurophilic granules A few neutrophilic leukocytes and perhaps an occasional myelocyte may be reported

Monocytic leukemia is recognized by the presence of large numbers of cells which can be definitely identified as monocytes.

The monocytes represent a separate series of cells and for this reason monocytic leukemia is separated from myelogenous and lymphatic forms of the disease. Reminiscent of former beliefs in regard to the origin of the monocyte and thus of the

different terminologies are the terms monocytic leukemia of the Naegeli type or monocytic leukemia of the Schilling type. The monocytic leukemia of the Naegeli

Proliferation and transitions to the freely circulating monocytic cells appear to depend on the age of the patient and the degree of stimulation A fulminating course in a young person will produce extensive reticulum hyperplasia because the maturation of the cells cannot keep pace with proliferation. In an older person a similarly acute course will produce less hyperplasia because the tissues are less adaptable to proliferation A heterogeneous accumulation of leukocytic elements, producing findings resembling those in Hodgkin's disease, may be present in acute instances. The brain may contain leukemic infiltrates and hemorrhages which are a contributory or an immediate cause of death.

Monocytic leukemia occurs more frequently in men between 40 and 60 years of age, although no age or sex is exempt.

The manifestations are those common to other acute and chronic forms of leukemia Necrotic ulcerations in the buccal cavity and pharynx, diversity and severity of skin lesions, attended by severe pain are the only manifestations observed more commonly in monocytic leukemia than in other forms of the disease.

The diagnosis is made by recognition of the immature monocytes in the stained blood smears In some instances it may be necessary to make histologic studies

In rare instances a monocytic leukemia is manifested as a chronic leukemia.

In rare instances acute or subacute *eosinophilic, basophilic* or mast cell, *neutrophilic,* and *plasma cell* leukemias may be observed In each of these leukemias the type of cell present is the only distinguishing feature.

Leukosarcoma refers to an acute leukemia characterized by the presence of the blood findings of an acute leukemia in a patient known to have lymphosarcoma (Hodgkin's disease).

By the time the patient is aware of a definite illness, the symptoms are those resulting from anemia, or the pressure of an enlarged spleen or liver, enlarged lymph nodes, or leukemic infiltrations in various organs and tissues Pain, limitation of movement, and other symptoms which suggest arthritis, osteomyelitis, or rheumatic fever are rare but when present may be due to pathologic fracture of bone which may occur in either acute or chronic leukemia Fractures are commoner in children who have acute myelocytic leukemia than in those who have chronic leukemia Sternal tenderness occurs in leukemia, but this is most commonly due to an associated esophagitis or peptic ulcer

Symptoms may arise as the result of compression by bony tumors on nerves or other structures A single bone tumor in chronic myelocytic leukemia is rare. These bone tumors are usually multiple Periosteal stripping, foci of bone destruction, and areas of osteoporosis occur and may cause bone pain Leukemic proliferation in the juxta-articular portions of the bone may give rise to symptoms resembling those of an acute arthritis

Many of these patients have symptoms attributable to the increased metabolic rate such as loss of weight, nervousness and abnormal perspiration As the disease progresses, cachexia is inevitable A few patients have chronic hemoptysis, or rectal bleeding and fever.

The abdominal symptoms in lymphocytic leukemia may appear at any time or late in the course of the disease In a small proportion of cases the first symptom may

be abdominal pain, continuous or intermittent, symptoms of intestinal obstruction; abdominal tumor or serious gastrointestinal hemorrhage.

On examination the patient may have a normally colored skin and appear healthy Some are pale and tired in appearance and show evidence of loss of weight Extreme enlargement of the spleen may be evident on inspection. The spleen is almost always palpable in all forms of chronic leukemia.

Lymph-node enlargement is uncommon early in myelocytic leukemia. As the disease advances, slight or very moderate enlargement is found. Lymphocytic leukemia contrasts sharply in this respect, for lymph-node enlargement appears early and may be extensive, involving all nodes The nodes are discrete, firm, and freely movable without tenderness

Cutaneous lesions may be the first symptoms of leukemia, the blood changes and other changes appearing later, or they may make their appearance at any time during the course of the disease The cutaneous lesions (leukemids) may resemble a nonspecific lesion which may be found in other conditions. The leukemids include vesicles, pustules, wheals, bullae, petechiae, hematomas, papules, nodules, herpes zoster and prurigo lymphatica Pigmentary changes may be present as well as sensory disturbances such as itching and burning The specific lesions for leukemia consisting of leukemic cells like leukemids are difficult of identification, except on biopsy Bleeding into the skin is common in acute leukemia and may occur in the late stages of chronic leukemia, especially in lymphocytic leukemia.

Herpes zoster may occur in leukemia and in rare instances may be followed by paralysis.

An erythroderma occurs in chronic lymphocytic leukemia which is characterized by progressive reddening of the skin, together with thickening and edema or thinning and atrophy The cutaneous involvement may be diffuse and generalized, and when the skin of the whole body is involved, the condition is the so-called universal leukemia cutis Localized erythroderma rarely occurs anywhere except on the face The lesions may be yellowish brown, red, bluish red or purplish, and they may be nodular. Ulceration and necrosis rarely ensue

Lesions of the skin are rare in *chronic myelocytic leukemia.* When skin lesions do occur they are described as firm, circumscribed, brownish, gray or bluish cutaneous and subcutaneous nodules varying in size, measured in millimeters to several centimeters The appearance of leukemic nodules in the skin in myelocytic leukemia is of immediate, grave prognostic import

In chronic lymphocytic leukemia enlargement of the tonsils may be a relatively early finding and may reach extreme proportions Enlargement of the tonsils in an elderly person should be considered as either leukemia or malignant disease until proved otherwise Very rarely the breasts or the salivary and lacrimal glands may be involved and present symmetric painless enlargements (Mikulicz's syndrome)

Exophthalmos is characteristic in chloroma It may be of unequal degree in the two eyes. Examination of the fundus reveals engorgement of veins, hemorrhages, exudates and blurring of the disk Infiltration by leukocytes may appear as white lines sheathing the peripheral portions of veins Often the ophthalmologist can suggest the diagnosis.

Occasionally in chronic myelocytic leukemia sudden blindness due to hemorrhage may occur in one eye Leukemic infiltrations may involve the iris, cornea, and sclera

Hemorrhage or infiltration in the external, middle or internal ear, or infiltrations along the course of the eighth nerve may produce deafness, otitis media or Ménière's syndrome.

Cough may be present and fine crepitant rales are often heard over the bases of the lungs. There may be atelectasis, mediastinal tumor from lymph node enlarge-

ment, or pulmonary infiltration or pleural effusion Such changes are much less frequent in the myelocytic form (see Mediastinal Tumors, Chapter 9).

Enlargement of the heart, systolic murmurs, tachycardia and edema are common findings Infiltrations in the myocardium are common, but myocardial failure attributable to leukemia is rare and the diagnosis cannot be made during life

In those who have had severe abdominal pain, manifestations of intestinal obstruction or hemorrhage may be responsible for the pain. On examination by the roentgenologist or the surgeon gross deformities are not present. The symptoms arise from an extensive cellular (lymphocytic) infiltration of the intestines. Consequently the term *pseudoleukemia gastrointestinalis* has been employed to designate these cases. In the stomach pseudoleukemia gastrointestinalis may closely resemble carcinoma

The liver is often enlarged. Jaundice and ascites are unusual.

In chronic myelocytic leukemia 9 of every 10 patients have enlargement of the spleen at the first examination. The spleen is smooth and hard and the notches in the border are easily felt The spleen may be extremely enlarged, and it may extend to the ilium laterally and around to the right anterior superior spine.

In chronic lymphocytic leukemia the spleen is not so large as in myelocytic leukemia It may extend only one or more fingerbreadths below the costal margin. It is very rare in chronic leukemia that neither the spleen nor the lymph nodes are enlarged but such lack of enlargement has been observed

The splenomegaly is painless and the spleen is nontender unless infarcts and perisplenitis are present and give rise to a degree of pain and tenderness as to suggest the presence of some abdominal emergency. A friction rub may be felt and heard over the spleen after infarction

Any part of the nervous system may be involved in leukemia, and the findings on physical examination are thus of wide range since they are produced by hemorrhage, thrombosis, infiltration with leukemic cells, or tumor-like masses

In *chronic myelocytic leukemia,* well-marked leukocytosis is the rule. A count of 30,000 to 40,000 is frequently found at the time the disease is first discovered. Lower counts may be encountered, even if the symptoms and the degree of anemia indicate far-advanced disease In some instances the count may be normal or low, as in aleukemic leukemia

The segmented neutrophils comprise most of the leukocytes. Metamyelocytes and myelocytes are found in great numbers Only a few undifferentiated myelocytes and only a small number of myeloblasts are found in chronic myelocytic leukemia Eosinophilic and basophilic myelocytes are increased sufficiently to maintain or exceed their normal numerical ratio The percentage of lymphocytes is relatively low.

In *chronic lymphocytic leukemia* the total leukocyte increase is seldom as great as in leukemia of the myelocytic type, the average being between 25,000 and 35,000 per cubic millimeter and comprised mainly of small lymphocytes Large lymphocytes not infrequently are found Immature lymphocytes occur less commonly.

Sternal aspiration is not performed as a diagnostic test in leukemia except when the diagnosis is in question

Chronic Megakaryocytic Myelosis. The syndrome of chronic splenomegaly —weakness, leukemoid peripheral blood findings and myelofibrosis with osteosclerosis—is described under a variety of terms. These include chronic nonleukemic myelosis, myeloid megakaryocytic hepatosplenomegaly, megakaryocytic nonleukemic myelosis and agnogenic myeloid metaplasia of the spleen

The liver and the spleen are greatly enlarged The sinusoids of the liver contain giant cells of megakaryocytic characteristics The basic splenic architecture may be

unaltered, but the extrafollicular parenchyma is filled with myeloid metaplasia containing megakaryocytes. The reticulum of the lymphatic sinusoids may contain large numbers of megakaryocytes. The bones are sclerotic. The megakaryocyte is regarded as the *sine qua non* of this chronic myelosis. The two forms of giant cells, megakaryocytes and Sternberg-Reed cells, are easily confused.

The symptoms and physical findings may resemble those of Hodgkin's disease with pulmonary involvement There may be dyspnea and cyanosis and wheezy expiratory rales The abdomen may be distended by the enlargement of spleen and liver Ricker has expressed the opinion that the process is probably malignant, an indolent myelogenous leukemia.

Aleukemic or Subleukemic Leukemia (*Leukopenic Myelosis*). The clinical features of leukemia without leukocytosis are similar to those of leukemia with leukocytosis Acute and chronic forms are encountered, and myelogenous, lymphogenous and monocytic types have been described The recognition of subleukemic leukemia is often difficult. The study of the sternal marrow is helpful

Chloroleukemia (*Chloroma*) Chloroma is usually of myelocytic origin However, a case of monocytic chloroma has been described The characteristic tumefactions are situated in relation to the periosteum and ligamentous structures of the skull, paranasal sinuses, orbits, spinal column, ribs and sacrum These tumefactions are observed more commonly in children and young adults than in older persons The general clinical manifestations simulate those of acute leukemia. The blood changes are indistinguishable Chloroma may cause protrusion of the eyeball, with diplopia and loss of vision, pain, deafness, and other cranial nerve palsies. Inside the skull or extending into the skull, chloroma causes the symptoms of pressure, infiltrative growths, or expanding tumors

A patient who has chronic leukemia may remain comfortable for years with cell counts of more than 100,000 cells

DIAGNOSIS OF THE LEUKEMIAS

The combination of glandular enlargement, splenomegaly, leukocytosis consisting mainly of immature leukocytes, and anemia is unmistakable

The immaturity of the leukocytes is of greater significance than the leukocyte count *itself*

Thrombocytopenia, with prolonged bleeding time, poor clot retraction and positive reaction to the tourniquet test, is an almost invariable accompaniment of acute leukemia

Aleukemic leukemia should be suspected whenever there are splenomegaly, lymphadenopathy, fever, purpura or retinal hemorrhages, swelling of the gums, deep bone pains, bone tenderness, pathologic fractures and bone tumors It is in these patients that sternal puncture has its most valuable application in leukemia.

The average duration of life following the onset of symptoms is between 3 and 4 years irrespective of treatment

ERYTHROCYTES (NORMAL AND PATHOLOGIC)

The erythrocytes are formed mainly from the sinusoids of the bone marrow but some arise from the spleen, lymph nodes, liver, suprarenal glands, cartilage, adipose and other tissues These cells are non-nucleated, round, inert bodies measuring on the average 7.2 to 7.9 microns in diameter. The erythrocyte is about two thirds water and about one third hemoglobin The hemoglobin is about two thirds protein and the rest is lipids and *inorganic salts*

The erythrocyte remains useful for about 120 days. A volume of packed cells equaling about 50 ml is destroyed daily, the fragments of these cells are phagocytized by the reticuloendothelial system The hemoglobin is changed to bilirubin, urobilinogen and urobilin for excretion in the feces and the urine

The erythrocyte contains no definite cell membrane though capable of withstanding much trauma during its circulation through the vascular system. Whether or not there is an outer cellular membrane, in the presence of hypotonic and hypertonic sodium chloride solutions the cell behaves as though there were a membrane.

The main function of the erythrocyte is to transport oxygen from the pulmonary capillaries to the tissues and to bring back carbon dioxide to be liberated by the lungs These mechanisms are described at length and in detail by both chemists and physiologists

The mechanism which regulates the number of erythrocytes in the normal circulating blood is not known At present all hypotheses are undergoing reconsideration in regard to the role of the vitamin B group (especially B_{12}) in erythropoiesis. Iron is necessary for hemoglobin formation, and it seems that copper too, as a catalytic agent, is essential to the process Protein is likewise necessary; hematopoiesis continues, however, when the protein intake is very low.

The stages of development of erythrocytes are designated by a variable terminology. Irrespective of stages of development it is well to consider the *megaloblast* to be the earliest form of erythrocyte which is recognized It is a large cell (12 to 18 microns in diameter) with a centrally placed round nucleus

The *erythroblast* is considerably smaller than the megaloblast and is the first of the series to contain hemoglobin in its cytoplasm

The *normoblast* is the usual nucleated erythrocyte observed in smears of peripheral blood.

The *erythrocyte* is the mature red blood cell It is a circular biconcave disk 6 to 9 microns in diameter and 1 micron thick

The following terms are used in description of erythrocytes Anisocytosis designates variations in size A microcyte is less than 6 microns in diameter. A macrocyte is greater than 10 microns in diameter. Poikilocytosis implies variations in shapes of erythrocytes. Variations in the staining properties of these cells are termed achromia, hypochromia, hyperchromia, polychromatophilia and punctate basophilia or polychromasia.

Variations in structure are implied by the employment of the following terms: Cabot's rings, Howell-Jolly bodies, reticulocytes and nucleated erythrocytes. Hematologists employ certain other terms in description of the variations in structure of the erythrocytes. a target cell is an erythrocyte which resembles a target used on a rifle range—a dark central zone, a light ring, and then a deeply stained outer rim Oval-shaped cells characterize ovalocytosis, a rare hereditary condition without known significance in white and colored races Spherocytes are erythrocytes that have lost their biconcave shape These cells characterize familial and acquired hemolytic icterus.

Variations in staining reactions are designated by the term basophilia or polychromasia. Romanowsky-stained preparations of blood reveal a limited number of erythrocytes which have been tinted a diffuse bluish color (Howell-Jolly bodies). This cellular reaction is termed basophilia. The term punctate basophilia or stippling is applied to erythrocytes showing discrete, bluish black granules after staining

Reticulocytes are made evident by vital staining technic and comprise from 0.2 to 0 8 per cent of the erythrocytes of normal blood. *Reticulocytes in increased numbers* are constant and dependable evidence of active regeneration It is believed that they disappear within a few days as the cells mature in the circulation. A sudden increase of these cells in the blood is termed a reticulocyte crisis. Such a crisis may occur within a few days after the institution of effective treatment in severe instances of pernicious anemia or after hemorrhages Reticulocytes are especially numerous in familial hemolytic jaundice.

Nucleated erythrocytes or normoblasts are approximately the size of a normal erythrocyte. The more nearly mature forms contain a nucleus which has a diameter less than two thirds of that of the erythrocytes It is round, and stains a dense, homogeneous, purplish black color without showing any structure (pyknotic). The cytoplasm may be normal or basophilic or may vary in degree of reaction to stains

The more primitive erythroblasts, which are present in some severe anemias, have nuclei and nucleoli The cytoplasm is abundant and is strongly basophilic.

Megaloblasts or *promegaloblasts* are the primitive cells of the erythrocytic series. These cells rarely if ever occur in the blood except in severe untreated pernicious anemia

Nuclear particles of the erythrocytic series differ from granules. When they are in the form of coarse granules, they are called Howell-Jolly bodies. They may also occur as filaments which are variously looped or curled (Cabot's rings). These may be present in any condition in which nucleated erythrocytes are present, and have about the same significance

ERYTHROCYTE COUNT. The erythrocyte count in newborn infants is about 5,500,000 per cubic millimeter of blood It falls rapidly during the first few weeks to about 5,000,000, and reaches a minimum (about 4,500,000) at one year During childhood it is somewhat lower than during adult life. In adult men it is about 5,500,000, in adult women, about 4,500,000 to 5,000,000 per cubic millimeter. The erythrocyte count fluctuates with changes in plasma volume, or with the storage of red cells in, or their release from, the spleen and other reservoirs. These fluctuations in values rarely exceed the fluctuations in the numbers of erythrocytes from error in counting.

In the clinical practice of medicine the average normal values for numbers of erythrocytes as reported from the laboratory are about half a million less than the foregoing values.

ERYTHROCYTOSIS. An erythrocytosis (polycythemia) signifies an increase above the normal in the number of erythrocytes in the circulating blood A transient erythrocytosis is present in the newborn infant and in adults during short exposures to high altitudes These increases are transient and are comparable to leukocytosis An erythrocytosis is due to the effect of anoxemia on the bone marrow which may stimulate excessive production of erythrocytes by some by-product of asphyxia. Commonly the anoxemia of erythrocytosis is due to impaired pulmonary ventilation, decreased atmospheric pressure, defective pulmonary circulation, or a reduction in the oxygen-carrying power of the hemoglobin. The usual causes for reduction of the oxygen-carrying power of the hemoglobin are the effects of various chemical agents and drugs with special reference to the coal-tar derivative aniline and its derivatives, phosphorus and cobalt.

ERYTHREMIA An erythremia denotes an absolute increase in the number of circulating erythrocytes due to an excessive production by the bone marrow (absolute polycythemia). The cause for this excessive production is unknown, and therefore erythremia is analogous to leukemia

HEMATOCRIT (VOLUME OF PACKED CELLS). The volume of packed cells obtained by centrifugation of whole blood is termed the hematocrit The average normal value of packed cells for men is 45 ml per 100 ml of blood, for women it is 42 ml.

ERYTHROCYTIC INDEXES (WINTROBE). There are certain indexes of the erythrocytes which are often used and referred to in the diagnosis of diseases and conditions involving the erythrocytes.

The *color index* is the quotient of the percentage of hemoglobin divided by the product of the first two figures of the erythrocyte count by two The normal index is 1

The *volume index* is the product of the number of *milliliters of packed* cells per 100 ml (the normal mean volume of packed cells is 43 2 ml per 100 ml of blood) and 2.3 divided by the product of the red cell count (millions per cubic millimeter) and 20

The [illegible] of packed

cells per

Normal [illegible]

The *saturation index* is the quotient obtained by division of the percentage [illegible] number of milliliters of packed erythrocytes per 100 ml

[illegible] he normal range is from 0 9 to 1 2

[illegible] is the quotient obtained by dividing the hemoglobin [illegible] by the number of erythrocytes in millions per cubic millimeter. The results are in micromicrograms

The normal range of values for adults is 29 (± 2) and for children, 26 to 28

Mean corpuscular hemoglobin concentration is the quotient obtained by division of 100 times the hemoglobin in grams per 100 ml. of blood by the volume of packed corpuscles in milliliters per 100 ml. The normal range for children is 32 to 34, for adults 34 (± 2).

OXYGEN-COMBINING POWER The blood of the normal young man has an average oxygen-combining capacity of 20 9 volumes per cent, corresponding to 15 6 gm. hemoglobin per 100 ml (Van Slyke). This value for the oxygen-combining power is too high for the average patient In practice 14 to 14.5 gm. of hemoglobin is to be considered the usual upper limit of the normal value.

HEMOGLOBIN. Hemoglobin is a conjugated protein consisting of iron in combination with protoporphyrin and globin It is found in the bone marrow and within the erythrocytes Hemoglobin forms an unstable compound with oxygen and on exposure to air in the lungs forms oxyhemoglobin, which enables it to carry oxygen to the tissues. In the tissues the oxygen is lost from the hemoglobin, and reduced hemoglobin is formed by the addition of carbon dioxide which is then transported to the lungs and exhaled

Hemoglobinometers are of three general types. (1) those based on direct matching of the unchanged blood with color scales (Tallqvist and Dare); (2) those based on the conversion of hemoglobin into acid hematin (heme) with matching colors (Sahli, Sahli-Hellige, Newcomer, Wintrobe, Haden-Hausser and Osgood-Haskins); (3) the photoelectric-cell method of Exton and Sheard-Sanford.

The American Society of Clinical Pathologists has decided that hemoglobin should be reported in terms of grams per 100 ml of blood The calculation takes into account the age and sex of the patient According to Wintrobe the average normal values in grams per 100 ml of blood from birth to adult age are as follows First day 19.5 ± 5, two to eight days 18 3 to 19 0 ± 4, two to eight weeks 14 0 ± 3 3, three to eleven months 11.8 to 12 2 ± 2.3, one to two years 11 2 to 11.8, three to ten years 12.5 to 12 9, eleven to fifteen years 13 4, adult males 16 0 ± 2 In practice it is the exception, not the rule, to find men who have a hemoglobin of 14 0 gm. or more Women have less.

Postprandial Variation in Hemoglobin. Branwood showed that the percentage of hemoglobin in the peripheral blood has a postprandial decrease of the order of 5 to 10 per cent This fall is in proportion to the size of the meal—the larger the meal the greater the fall There is also, presumably, a fall in the number of erythrocytes at this time This decrease in hemoglobin is probably due to a redistribution of the cells from the periphery to the abdominal viscera and possibly also to slight changes in blood volume This fall in hemoglobin can be prevented by exercise or by the administration of epinephrine Patients who have hypertension and hyperthyroidism do not share this postprandial decrease in hemoglobin.

Hyperchromia is an increase in the total amount of hemoglobin whereas oligochromia designates a decrease

BLOOD IRON The absorption and utilization of iron in the human organism are of interest and importance because of the frequent therapeutic need for this element. The importance of hydrochloric acid and ascorbic acid (vitamin C) in the release and the reduction of iron to the ferrous state in the stomach of human subjects is certain Protein digestion products also appear somewhat effective in the release of iron Hence, ascorbic acid and dietary protein may actually increase the availability of food iron

It has been demonstrated that the beta fraction of the serum globulins transports the serum iron In cases of iron deficiency anemia the serum iron value is much less than normal (normal values 0 08 to 0 17 mg per 100 ml). The iron-binding globulin is only about 9 per cent saturated The degree of saturation in hemochromatosis and transfusion hemosiderosis is nearly 100 per cent

Little or no iron is excreted in the urine and only small amounts are eliminated in the feces, probably by way of the bile This concept visualizes the human organism as a tight compartment, as far as iron is concerned, and further implies that little or no absorption of exogenous iron into the closed space occurs other than to replace blood

loss A significant amount of iron may be excreted in human sweat by the normal adult male subject.

In vitro studies, in which radioactive iron (as Fe^{59} or Fe^{55}) is used as a tracer, present convincing evidence that heme synthesis occurs in the immature erythrocyte itself. The rate of iron uptake is greatest in the normoblast, but even the reticulocyte shows a definite uptake. The radioactive iron is present in the recrystallized heme obtained from the hemoglobin of these cells Addition of either folic acid or liver extract to the immature erythrocyte increases the rate of heme synthesis, as manifested by an increased rate of iron uptake.

The normal iron content of the blood is 40 to 60 mg. per 100 ml, averaging about 52 mg. in males and 45 mg in females Practically all of this is in the red blood cells in the form of hemoglobin (15.6 gm. per cent). The inorganic iron content of whole blood averages only about 1 to 1 7 mg. per 100 ml There is a small amount of inorganic iron in the plasma or serum, 0 08 to 0 17 mg per 100 ml This value is rather constant in the fasting state and is probably an index of the activity of the intermediary metabolism of iron, particularly destruction and production of hemoglobin About 90 mg of iron is liberated daily by normal breakdown of erythrocytes

After ingestion of *inorganic iron salts*, the plasma iron concentration rises to maximal levels of about three to four times the fasting level in about 2 to 4 hours, subsequently declining gradually over a period of 6 to 12 hours, depending on the dosage Thus the plasma appears to be the medium of transportation of iron from the intestinal tract to the tissues in which it is further utilized or stored Absorbed iron is transferred to the erythrocytes with remarkable rapidity, as has been demonstrated by radioactive iron.

The *plasma iron* is influenced by and may be regarded as a measure of the quantity of iron absorbed from the intestine, the adequacy of the iron reserves of the tissues, the capacity of the bone marrow to utilize iron in hemoglobin synthesis, and the activity of hemolytic processes

Disturbances in the metabolism of iron are evidenced by a decreased hemoglobin formation, decrease in circulating hemoglobin, or abnormal deposition of iron-containing pigment in the tissues (hemosiderin) Certain forms of hypochromic and microcytic *anemia* are dependent on inadequate supply or absorption of iron.

Iron deficiency may also occur as a result of *hemorrhage*, with consequent exhaustion of the available tissue reserves of this element. Low values for plasma or serum iron have been reported in hemorrhagic and hypochromic types of anemia High values are present in forms of anemia, such as pernicious anemia, characterized by diminished hemoglobin formation not due to iron deficiency

Deposition of excessive amounts of iron-containing pigment (hemosiderin) in the tissues occurs as a result of excessive breakdown of erythrocytes in hemolytic types of anemia, in conditions in which hemoglobin synthesis is inadequate owing to factors other than iron deficiency (pernicious anemia), and in hemochromatosis, the cause of which is unknown. In the latter condition enormous amounts of iron may be deposited in the tissues, particularly in the liver, pancreas and retroperitoneal lymph nodes

Hemoglobinuria. Paroxysmal Cold Hemoglobinuria. In the syndrome of paroxysmal cold hemoglobinuria the intravascular hemolytic reaction is dependent on the presence in the serum or plasma of a hemolysin, which is absorbed by the erythrocytes only at low temperatures Complement is not necessary for this phase but is essential for hemolysis to occur when the body is rewarmed (the Donath-Landsteiner reaction) The serum of patients who have paroxysmal cold hemoglobinuria will hemolyze the red blood cells of other persons in the same blood group, but the erythrocytes of patients with this condition are not lysed by the serum of normal persons. This hemolysin is distinct from the Wassermann reacting substance (that is, reagin), and there is no correlation between the titer of the complement fixation or flocculation tests for syphilis and that of the hemolysin, except that both usually decrease following antisyphilitic therapy.

Evidence that this disease is caused by syphilis seems well established, but the mechanism remains obscure. The coexistence of active clinical syphilis and paroxysmal cold hemoglobinuria is uncommon This condition occurs in latent syphilis or occasionally in dementia paralytica. The finding of the Donath-Landsteiner hemolysin in patients with late syphilis has varied from less than 0 2 per cent to 20 per cent. In a study by Donath and Landsteiner of 93 patients who had dementia paralytica, only 1 patient was found to have paroxysmal cold hemoglobinuria, but 6 others had a positive Donath-Landsteiner reaction without clinical manifestations of hemoglobinuria

SYMPTOMS After exposure to cold the patient soon experiences muscular aches and pains, abdominal cramps, headaches, nausea and vomiting Certain patients manifest vasomotor disturbances such as urticaria, or Raynaud's phenomenon may occur. Shortly after exposure to cold the patient experiences a shaking chill, the severity of which is dependent on the degree of hemolysis. The patient's temperature may rise to 102 or 104 F (38.3 or 40 C) If large numbers of erythrocytes are hemolyzed, the patient may be definitely jaundiced.

On examination the patient is weak and the blood pressure may be low. The liver and the spleen are occasionally palpable during the attack

One to four hours after chilling, the urine becomes dark red, wine or mahogany in color It frequently contains albumin, casts and even a few erythrocytes. Spectroscopic examination reveals that the color is due to oxyhemoglobin, methemoglobin and sometimes hematin The erythrocyte count and hemoglobin content may drop decidedly after an attack An initial neutropenia occurs during the exposure to cold, followed by leukocytosis in the chill phase. The blood serum is colored pink, and in severe instances the serum bilirubin may be elevated. Reaction to the serologic test for syphilis is almost always positive If the patient gives persistently negative reactions to tests for syphilis, the diagnosis of paroxysmal cold hemoglobinuria should be questioned

The majority of patients who have paroxysmal cold hemoglobinuria usually manifest *a positive response to Ehrlich's test This test consists of binding the finger with a liga*ture and immersing it in ice water for a few minutes. After the finger is warmed, local hemoglobinemia can be demonstrated This reaction is less hazardous than the reaction to the Rosenbach test and is preferable in the investigation of patients who have hemoglobinuria The *Rosenbach test* consists of immersing the hands or feet in ice water for 10 to 20 minutes The resulting hemolysis may produce severe constitutional symptoms and has occasionally resulted in anuria Repetition of the cold water test may cause sufficient depletion of the patient's complement that negative reactions are obtained

The *Mackenzie* "rough" test consists of chilling a sample of the patient's blood in ice water A positive result is denoted by hemolysis after the blood is rewarmed In the Donath-Landsteiner test a mixture of the patient's erythrocytes, varying dilutions of his serum and guinea pig complement, is immersed in ice water and then rewarmed Hemolysis of the patient's cells is a positive result. Appropriate controls are necessary for interpretation of results in these tests

DIAGNOSIS The diagnosis is based on the foregoing findings, the history of exposure to cold, and the presence of hemoglobinuria

Differentiation from other types of hemoglobinuria is usually relatively simple In the *Marchiafava-Micheli syndrome* the hemoglobinuria occurs only at night. The Donath-Landsteiner reaction is negative in both the Marchiafava-Micheli syndrome and march hemoglobinuria, but positive in cold hemoglobinuria Paroxysmal cold hemoglobinuria is differentiated from that caused by cold hemagglutinins by the finding that hemolysis occurs while there is exposure to ice water, and that rewarming is not necessary for the hemolysis

March Hemoglobinuria. Like orthostatic albuminuria, march hemoglobinuria occurs after exercise in the upright position It often affects soldiers The urine be- [illegible] and brown after the march and the color persists for several hours

afterward. The color is due to the presence of hemoglobin. For practical purposes the condition is symptomless.

Hemolytic Anemia With Paroxysmal Nocturnal Hemoglobinuria. Chronic hemolytic anemia with paroxysmal hemoglobinuria is characterized by hemolytic anemia and attacks of nocturnal hemoglobinuria. It is a rare and curious disorder, the cause of which is unknown.

Venous thrombi may be found in the systemic or portal circulation. There are hepatomegaly with central zone necrosis, moderate splenomegaly with little deviation from the normal, and marked erythropoietic hyperplasia of the bone marrow. The kidneys may be enlarged. Hemosiderosis is found but it is peculiar in distribution. Free iron pigment is present in large amounts in the kidneys (convoluted tubules and ascending loops of Henle), but only traces are found in other organs.

Men are affected somewhat more frequently than women, most often in the third decade of life The attacks of hemoglobinuria are unrelated to cold, but it may have been noticed that urine which was passed during the night, or that passed when the patient arises in the morning, is dark, whereas the day urine may appear normal Weakness and yellowish discoloration of the skin and mucous membranes may be the first and only symptoms for many years, or abdominal, lumbar or substernal pain and fever may usher in an attack of hemoglobinuria.

Examination reveals jaundice, or a bronzing and pallor of the skin The spleen and the liver are enlarged. The tongue is normal and so is the nervous system.

There is macrocytic or normocytic anemia Reticulocytosis (10 to 20 per cent), polychromatophilia, normoblasts and macroblasts are present in the stained blood smear Leukopenia and thrombocytopenia are common The van den Bergh reaction is increased and indirect Spectroscopic examination reveals free hemoglobin in the plasma.

The urine contains increased amounts of urobilinogen Hemoglobinuria may be present. The urine sediment is yellow and gives a positive iron reaction

On examination of the bone marrow, normoblastic hyperplasia is the characteristic finding.

A very simple diagnostic method is the heat resistance test, in which a test tube containing about 5 ml of blood obtained by means of a dry-air sterilized syringe is placed into an incubator for 6 to 24 hours at a temperature of 98.6 F (37 C). In cases of nocturnal hemoglobinuria, hemolysis occurs which can be seen with the naked eye.

The forementioned findings are diagnostic. Congenital chronic hemolytic anemia with nocturnal hemoglobinuria is distinguished from congenital hemolytic jaundice by the negative family history and the absence of increased fragility of the erythrocytes to hypotonic saline solutions

The failure of cold to activate hemolysins distinguishes this condition from paroxysmal hemoglobinuria e frigore The finding of malarial parasites or *Bartonella bacilliformis* will aid differentiation from blackwater fever or bartonellosis Sickle cell anemia is recognized by the finding of sickle cells in wet films

Transfusions are avoided.

Anemia. Anemia is a decrease below the average normal quantity (12 to 14 gm per 100 ml) of hemoglobin in blood This may or may not be accompanied by a decrease in the number of erythrocytes Before proceeding with further discussion of blood dyscrasias it is well to discuss the ill effects of a simple anemia since these are almost always a part of the symptomology of a blood disease.

The number of erythrocytes per cubic millimeter may be reduced by (1) blood loss or an increased blood destruction, (2) decreased blood production or (3) faulty production of cells It is on these three categories of blood depletion that the various classifications of anemias are based

The terminology used in the description of an anemia may be based on the size of the cell and its staining reactions For instance, in the vernacular of the hematologist anemias are often termed normocytic, macrocytic and microcytic.

In *normocytic anemia* there is a proportionate decrease in the number of corpuscles, the quantity of hemoglobin, and the volume of packed erythrocytes. The erythrocytes have not, on the average, been changed in size or hemoglobin content.

In *macrocytic anemia* the majority of the red corpuscles are larger than normal The volume of packed cells is greater than would be expected from the cell count. The hemoglobin content is normal in proportion to the volume of each cell but owing to size the hemoglobin content is greater than that of normal cells

In *microcytic anemia,* owing to the smallness of the erythrocytes, the volume of packed cells is less than would be expected from the erythrocyte count.

In regard to the staining reactions of the cells the term *hypochromic anemia* is often employed In hypochromic anemia there is a greater decrease in hemoglobin than in the volume of packed cells The corpuscles also are usually reduced in size, and thus the term *hypochromic microcytic anemia* may be appropriate

Symptoms of Anemia. The reduction in the oxygen-carrying power of the blood and the degree of change in total blood volume are responsible for the symptoms of anemia from any cause. In addition to these symptoms of anemia there are often other symptoms caused by the disease producing the anemia.

The adjustment to the reduced oxygen-carrying power of the blood may be so effective that an erythrocyte count of 2,000,000 cells per cubic millimeter and a hemoglobin of 6 gm per 100 ml may be borne with comfort if excessive physical exertion is not practiced However, a history will usually reveal that these patients are "symptomless" but not up to their normal standards of health. The symptoms of oxygen deprivation develop when about one half of the blood has been lost. The most prominent symptoms following the sudden loss of blood are those of shock, already discussed In elderly patients who have arteriosclerosis of the coronary arteries angina pectoris may be present

When there is *rapid destruction of blood,* the manifestations of the anemia result from the disposal of the products of blood destruction These manifestations are jaundice and hemoglobinuria, and abdominal pain

Skin and Mucous Membranes Chronic pallor of the skin and mucous membranes is due to many different causes (see Chapter 8). One of the causes of a chronic pallor is anemia A waxy, dead whiteness of the skin is present in acute loss of blood Chronic intermittent loss of blood is one cause of a distinctly sallow color. The greenish sallowness once considered pathognomonic of chlorosis is observed in both young women and young men and many of them are not anemic The lemon yellow pallor in pernicious anemia is a figment of the imagination.

Respiratory System The occurrence of respiratory symptoms in those who are anemic depends on the rapidity of the production of anemia, its severity, and the reserve capacity of the cardiovascular system A rapidly developing anemia is attended by breathlessness, tachycardia and pallor

Heart In direct proportion to the reduction of hemoglobin there are palpitation, tachycardia and breathlessness on exertion. The blood pressure may be slightly lowered but the pulse pressure is high In severe anemia the blood is carrying sufficient oxygen to supply the tissues while the patient is at rest, but on exertion dyspnea is evident In more severe anemia, dyspnea may occur while the patient is at rest

Cardiac dilatation may occur in severe degrees of anemia, bringing on a functional insufficiency of the mitral and tricuspid valves and, in rare instances, of the aortic valve also In severe anemia of any type the circulatory rate is increased, with elevation of pulse pressure, stroke volume, minute volume, cardiac rate and output, and oxygen consumption, and with a decrease in the arm-to-tongue circulation time. When the hemoglobin content is less than 3 5 gm., congestive heart failure may ensue even in the absence of pre-existing heart disease Heart failure does not leave any permanent damage if the anemia is quickly and effectively treated.

In some instances of severe anemia, angina pectoris may supervene in the

absence of manifest coronary artery disease. The angina pectoris, like congestive failure, clears on adequate treatment for the anemia

A severe degree of anemia appearing in a patient who has organic heart disease causes an accentuation of the existing symptoms, or if no symptoms are present, may cause symptoms to appear

A severe anemia is accompanied by dependent edema.

Electrocardiographic abnormalities are common in severe anemia. The abnormalities consist of flattening or inversion of the T waves, depression of the S-T segments, and a tendency to low voltage of the QRS waves. With correction of the anemia the electrocardiogram usually returns to normal

The Quantity of Red Blood Corpuscles in Heart Failure. The quantity of erythrocytes labeled by the Hevesy method has been estimated in cardiac patients both in the stage of decompensation and after compensation has been restored In decompensated cardiac patients there is an increase not only in the total quantity of blood and plasma but also in the mass of erythrocytes After compensation is restored, both the plasma and blood corpuscles decrease in quantity. There is a difference in the quantity of blood corpuscles, measured in grams per kilogram of dry body weight (the weight of the body when there is no edema), in decompensated patients and in normal subjects In decompensated patients the quantity of erythrocytes, as measured by Nylin and Hedlund, is on the average, 36 4 gm per kilogram of dry body weight, in normal subjects this value is 31.2 gm About the same quantity of erythrocytes is found in compensated cardiac patients as in normal subjects Estimation of the circulation time by this method in cardiac patients with dilated hearts but no peripheral edema supports the view that blood is retained in dilated hearts and that this factor greatly influences the estimation of the circulation time

Nervous Symptoms The symptoms of headache, vertigo, faintness, increased sensitivity to cold, tinnitus or roaring in the ears, black spots before the eyes, muscular weakness and easy fatigability, irritability, lack of power of concentration, and restlessness or drowsiness are essentially of nervous origin It is well to emphasize, however, that chronic irritability of disposition and mental ill health are not necessarily due to anemia.

Paresthesias may be encountered in chronic hypochromic anemia Paresthesias and extensive peripheral nerve and spinal cord disease are common in pernicious anemia

Gastrointestinal Symptoms The symptoms such as anorexia, nausea, flatulence, constipation, diarrhea, and vomiting are symptoms of failing health or accompanying digestive disease but are not necessarily due to anemia Other than the participation of the gastrointestinal tract in the debilities caused by an anemia, there are no symptoms

Genitourinary Symptoms A chronic hypochromic anemia may be caused by menorrhagia Once such an anemia is present, it may remain until the cessation of menstruation Albuminuria is common and there may be evidence of distinct impairment of renal function in those who have anemia There are two reasons for this: (1) A mild chronic glomerulonephritis, a pyelonephritis, or long-standing urinary infection may cause an anemia (2) The anemia itself may impair renal functional activity, for improvement in the anemia may be followed by clearing of the urine An acute glomerulonephritis attended by severe anemia has a poor prognosis Hyperazotemia causes an anemia

Metabolism In severe anemia the basal metabolic rate may be increased In leukemia such an increase is common and may be expected if a low-grade fever is [illegible] fever. A fever

may be increases in the concentration of blood urea (45 to 50 mg per 100 ml. of blood)

CONGENITAL AND FAMILIAL HEMOLYTIC DISEASES

Erythroblastosis. Hemolytic disease of the newborn may be manifested as hydrops fetalis, icterus gravis neonatorum, or congenital anemia of the newborn The condition is caused by iso-immunization of the mother during pregnancy; usually, however, by iso-immunization by an Rh-positive fetus during a previous pregnancy, or by blood transfusion prior to the beginning of pregnancy

The Rh Factor. The ill effects of transfusion of an Rh-negative woman with Rh-positive blood are known only well enough to result in confusion fraught with possible serious consequences Some young couples have been advised not to have children because the husband is Rh positive and the wife Rh negative.

The evidence indicates that an Rh-negative woman married to an Rh-positive man is almost certain to have at least one normal child unless she has received transfusions of Rh-positive blood Transfusions of Rh-positive blood may cause the first child to have erythroblastosis.

Now by appropriate laboratory procedures it is possible to detect Rh sensitization in almost all of the women who have babies with erythroblastosis Detection of sensitization during pregnancy often means erythroblastosis in one of its forms in the infant The exception to this rule occurs in women in whom antibodies have been formed during a previous pregnancy It is well to know about the presence of such antibodies in a multipara, for a sudden increase in antibodies indicates the presence of an Rh-positive fetus with likelihood of erythroblastosis. In such instances, it is only a likelihood, for there are women in whom antibodies were demonstrated during pregnancy who gave birth to healthy Rh-positive infants.

PATHOLOGY Icterus, edema, pallor, effusions in the serous cavities and sometimes petechiae are present Extramedullary hematopoiesis is present in the liver, spleen, kidneys, and adrenal glands In the macerated fetus the finding of erythroblasts in the pulmonary capillaries may be diagnostic The liver and the spleen are enlarged and there is hyperplasia of the bone marrow

SYMPTOMS Unless the mother has been immunized from blood transfusion of Rh-positive blood, the first one to three children may be unaffected However, once the disorder has appeared, succeeding pregnancies terminate in the birth of either an affected infant or a macerated fetus

An anemia present at birth, in the absence of hydrops or icterus, may be referred to as congenital anemia of the newborn In this form of the disease, if the child lives, there are dyspnea, cardiac enlargement and systolic cardiac murmurs if the anemia is severe

In the hydropic form, in which there is a generalized edema of the fetus, the disease is usually fatal prior to birth There is effusion in the pleural, pericardial and peritoneal cavities The liver is enlarged

In the icteric form of the disease the child is born alive and jaundiced at birth, or the icterus appears within one or two days. The spleen and the liver are enlarged

In some instances features of each of the three forms of the disease may be present

Less frequent manifestations of the disease are purpura and melena. When there is melena, there is hepatic and splenic enlargement, and perhaps hepatic cirrhosis

Cerebral symptoms may be present and due to spontaneous intracerebral hemorrhages The cerebral signs consist of convulsions, twitchings, opisthotonos and respiratory difficulties If the infant survives, there may be choreo-athetosis, extrapyramidal spasticity and mental retardation

The development of *kernicterus* has been attributed to the formation of small clumps by the agglutinated erythrocytes which plug the smaller arterioles of the brain to produce ischemic infarcts and to damage the liver It has been suggested that in the presence of jaundice the anoxemic ganglion cells of the nuclear masses take up the bilirubin, thus becoming stained in vivo

Congenital anemia of the newborn infant is often present at birth and it is not accompanied by hydrops or jaundice Often the infant lives only a few days However, if it survives, the anemia is well developed by the third or fourth day and is more marked by the end of a week. If there continues to be a severe anemia, the heart enlarges.

Icterus neonatorum, in contrast to icterus gravis, usually has its onset about the third day after birth and is not associated with severe anemia or enlargement of the liver and spleen. The number of nucleated cells in the circulating blood is not greater than the leukocytes and even these disappear within two or three days.

EXAMINATION The findings on physical examination depend on the manifestations which have been enumerated There may be a green coloring of the deciduous teeth due to deposition of pigment in the enamel. Roentgenographic examination reveals markedly increased density of the bones.

The nucleated erythrocytes of every stage of maturation are present in large numbers They greatly exceed the leukocytes in number even though there is a leukocyte count of from 15,000 to 30,000 per cubic millimeter. The erythrocytes are macrocytic and well filled with hemoglobin The hemoglobin concentration is normal Often by the third or fourth day of life the erythrocytes have decreased in number, and a profound anemia may be present.

The van den Bergh reaction may be indirect if damage to the hepatic cells and obstruction of the bile ducts have not occurred

DIAGNOSIS. A definite diagnosis can be made only if there is an appropriate combination of agglutinogens and agglutinins in the mother, the child and the father If a woman has erythrocytes which are Rh-negative and if she has had a stillbirth or miscarriage after one or two normal deliveries, or if she has had blood transfusions and since these transfusions has had an abortion, *erythroblastosis fetalis* is suspected Roentgenologic examination may be diagnostically helpful if there is revealed a "halo" about the fetal head due to edema of the scalp.

The most important factor from the standpoint of the life of the child is the readiness of suitable Rh-negative blood for transfusion.

Erythroblastic Anemia (Cooley's Anemia, Thalassemia). Erythroblastic anemia begins in early life, and in the United States persons affected are of Italian, Greek, Syrian or Armenian parentage

The etiology of aberrations of the erythrocytes in erythroblastic anemia is not established. The anemia represents a hereditary anomaly of the erythrocytes which is inherited as a recessive characteristic In the heterozygous individual the symptoms are mild, if present at all (thalassemia minor) The disease arises when both parents are affected and the homozygote, the patient, manifests the anemia (thalassemia major). It has occurred in identical twins

PATHOLOGY. There are present an increased destruction of erythrocytes, a bone marrow hyperplasia, a liberation of immature erythrocytes, a hemolytic process of a compensatory nature, and a defect in pigment metabolism. There are evidences of an active formation of blood, both medullary and extramedullary, splenomegaly, changes in the bones, and pigmentation of various organs resembling that of hemochromatosis The erythrocytes seem to be formed with an adequate or excessive membrane so that they can absorb more fluid without bursting than can normal cells.

SYMPTOMS. The child has been pale and weak since birth In many instances there has been a gradual enlargement of the abdomen with loss of weight. Often the disease is found when the child is examined on account of the symptoms of acute infection or disease.

EXAMINATION. The child has a large head and is small for its age The cheek bones and the cranial bones are thickened, the bridge of the nose is small, the eyelids are puffy, and there may be an epicanthal fold (mongoloid facies). The skin is pale and yellowish brown Cardiac dilatation is often present, and in advanced stages there are edema and effusion into serous cavities and ecchymoses. Spontaneous bleeding may be present. The abdomen may be large and often there is ascites The liver and especially the spleen are enlarged There is often edema of the legs and feet

Roentgenograms reveal changes in the skull, the frontal bones, the metacarpals, and the distal ends of the femora The changes consist of medullary trabeculations and thickening of the skull with thinning of the outer and inner tables, osteoporosis, and perpendicular striations of the diploe

The anemia is a hypochromic, microcytic type, and nucleated erythrocytes are present and may be numerous The majority of the nucleated erythrocytes are normoblasts and microblasts The van den Bergh reaction is positive, indirect

The leukocytes are increased in number, counts of 10,000 to 25,000 per cubic millimeter being common There may be present myelocytes and myeloblasts

DIAGNOSIS The important features of the disease diagnostically are mongoloid facies, splenomegaly, skeletal changes and severe anemia The erythrocytes are thin and of various shapes and sizes. Erythroblastosis, polychromatophilia, stippling, reticulocytosis, leukocytosis and slight icterus are usually present.

The resistance to hemolysis by hypotonic saline solution distinguishes the condition from congenital hemolytic jaundice and from sickle cell anemia The racial and familial incidence helps to distinguish Cooley's anemia from other erythroblastic anemias which may be present in infants and very young children

The fully developed disease is fatal An intercurrent infection is the usual cause of death In less severe instances death does not occur The degree of severity ranges from the comparatively fulminating disease seen in infancy to a benign anomaly producing little or no impairment of health which may be present at any age (the so-called thalassemia minor)

Thalassemia Minor. Thalassemia minor is observed in adolescents and adults of Mediterranean ancestry It has the features of thalassemia major, but they are of a much milder degree It too is apparently an inherited defect in hemoglobin synthesis resulting in cells of poor grade which nevertheless possess more than adequate membrane, so that they can absorb more fluid than normal cells without bursting Because of their thinness, they appear as bizarre forms

These patients usually have hypochromia and microcytosis of the erythrocytes with or without anemia and occasionally associated with abnormally high erythrocyte counts Stippled, oval cells, out of proportion to the degree of anemia, are the morphologic abnormalities present in the red corpuscles The resistance of the erythrocytes to hemolysis in hypotonic sodium chloride solutions is increased. The anemia is refractory to iron therapy Splenomegaly and slight icterus may be present

Sickle Cell Anemia. Sickle cell anemia is a hereditary and familial form of chronic, hemolytic anemia In addition to the anemia there are rheumatoid manifestations, leg ulcers and acute paroxysms of pain The characteristic shape that the erythrocytes assume in sickling is an abnormality of the cells and not of the blood plasma

Sickle cell anemia is apparently the only known disease that is completely confined to a single race, the Negro race Many instances of sickle cell anemia had been demonstrated in American Negroes before the disease was found to occur in Africa, the accepted place of its origin

The true sickle cell anemia or its related condition, sicklemia, occurs only in Negroes, Cubans, Mexicans, Italians, Greeks, Arabs, Portuguese, Egyptians and

South Americans The people other than Negroes in whom the disease is found are either members of the so-called Mediterranean races who, anthropologists say, as a result of their proximity to Africa have acquired a considerable admixture with the Negro race, or are white Americans whose families have at some time lived in or near the former slave states or metropolitan areas. The slave trade with Africa, participation of Negroes in European wars, and other circumstances of history brought the Negro race into close contact with many groups of white people and resulted in a wide diffusion of African stock. Ogden has expressed his conviction that the presence of the trait is a definite proof of an admixture in the immediate or remote ancestry

Several theories of the genetics of sickle cell anemia have been advanced. The homozygous-heterozygous theory suggests that there is a gene in Negro populations which when heterozygous results in sicklemia and when homozygous results in sickle cell anemia, a situation analogous to that which exists in familial erythroblastic (Cooley's) anemia

Sickle cell anemia has been diagnosed in infants less than 1 year of age but usually occurs in young adults There is no sex predisposition.

PATHOLOGY The spleen loses its normal structure and becomes infarcted, fibrotic and atrophic. The changes increase until the organ becomes a small fibrotic mass. The liver is enlarged and congested The bone marrow is hyperplastic The cortex of the bone is thickened and sclerotic but shows areas of medullary invasion and of necrosis Hemosiderosis is found in the kidneys, liver, spleen, lymph nodes and bone marrow.

SYMPTOMS Weakness and fatigability are commonly present. Episodes of pain in the joints or in the extremities often occur. Severe, stabbing, abdominal pain of sudden onset may be referred to any part of the abdomen Prostration and abdominal distention may be associated, and these symptoms may simulate those of an abdominal emergency. The leukocytosis which is usually found in patients who have this disease only adds to the diagnostic difficulty when an acute abdominal condition is suspected which seemingly should be treated surgically

Attacks of pains in the extremities are common but are rarely associated with redness, tenderness or swelling of the joints.

Sickle cell anemia progresses to an ultimately fatal outcome Death may occur from infections, cardiac or renal failure, and thrombosis or hemorrhages involving vital tissues Gallstones may form and cause symptoms

EXAMINATION. In sickle cell anemia the patients are usually underweight, the trunk is short, the extremities are long, and the habitus is linear with comparatively narrow hips, shoulders, hands and feet Kyphosis, scoliosis, saber shins, and tower-shaped skulls may be observed In both children and adults there may be an increased upper thoracic kyphosis and lumbar lordosis and the thorax may be increased in anteroposterior diameter The scleras are jaundiced There may be fever and generalized abdominal tenderness, and palpable liver and spleen Chronic unilateral or bilateral leg ulcers over the malleoli may be present These ulcers are deep and usually single, but multiple ulcers sometimes are present

The heart is enlarged, and a systolic murmur of variable intensity, depending on the degree of anemia, is often present

If the patient is critically ill, neurologic findings such as paresthesias of the extremities, drowsiness, stupor or coma, hemiplegia, aphasia, convulsions, stiffness of the neck, irritability, nystagmus, pupillary changes, blindness (temporary or permanent) and cranial nerve palsies may be present. The cerebrospinal fluid is usually normal

Examination of the blood may reveal a severe anemia The anemia is usually normocytic but in some instances, in severe anemia, it may be macrocytic. A reticulocytosis, nucleated erythrocytes, polychromatophilia, basophilic stippling, and sometimes Howell-Jolly bodies are present.

The characteristic phenomenon in this disorder is the change which can be observed to take place in the shape of the erythrocytes *when a drop of blood is sealed under a coverslip on a slide or in test tubes* In such preparations a few bizarre, multipointed forms (sickling) may be seen immediately, but changes occur at a maximal rate in 2 to 6 hours after the blood is drawn.

Leukocytosis is regularly present in sickle cell anemia It may be marked when excessive blood destruction is going on There is often a shift to the left, and there is a moderate number of myelocytes. Eosinophilia is not infrequent and the monocytes may be increased in number

Platelets are increased in number (300,000 to 500,000 per cubic millimeter) and bizarre forms may be observed The *sedimentation* of the corpuscles is slow. There are *hyperbilirubinemia* and increased urobilinuria of varying degree. The van den Bergh reaction is indirect Studies of bone marrow do not distinguish this from other forms of hemolytic anemia

DIAGNOSIS Diagnosis of sickle cell anemia is made by observing sickling of the erythrocytes in wet preparations, in conjunction with an anemia and signs of active erythrocytic regeneration, leukocytosis, and bilirubinemia Sickling alone is not sufficient, for it only indicates the presence of the sickle cell trait which may be the only abnormality present In a Negro patient who has severe abdominal pain, muscle spasm, leukocytosis and anemia the blood should be tested immediately for sickling before the appendix is removed or the pelvis is surgically explored.

Familial hemolytic jaundice has much in common with sickle cell anemia but, in addition to being very rare in Negroes, it is characterized by increased fragility rather than increased resistance of the erythrocytes in hypotonic saline solutions.

Congenital Hemolytic Jaundice. This chronic form of hemolytic anemia and jaundice is known also as chronic familial jaundice (icterus) hemolytic splenomegaly, chronic acholuric jaundice, and spherocytic or globe cell anemia

The disease is characterized by splenomegaly, spherocytosis, and diminished resistance of the erythrocytes to hemolysis by hypotonic saline solutions The disorder may not be sufficiently severe for recognition until late adult life

ETIOLOGY Genealogies of three and even four generations reveal that the trait is a mendelian dominant and is transmitted by either parent Some of the offspring are free of the disease.

PATHOLOGY It seems that the fundamental abnormality is an unusual thickness of the erythrocytic walls so that the cell approaches a sphere in shape, these spherical cells are easily destroyed by the spleen Surgical removal of the spleen thus removes the source of erythrocytic destruction

The *spleen* is enlarged, free of adhesions and weighs 1,000 to 2,000 gm The *liver* usually is not enlarged, nor is it usually cirrhotic, but the quantity of iron pigment may be increased Gallstones may be present in the gallbladder. The *kidneys* and the *lymph nodes* may contain increased blood pigment (hemosiderosis)

The *bone marrow* is hyperplastic *Heterotopic masses of bone* have been observed alongside the vertebral column in the thorax and in the renal pelvis

SYMPTOMS The symptoms may be manifested at birth or in childhood or adolescence

The icterus is not intense The complexion is constantly sallow. Increase in destruction of blood may be of sudden onset and is manifested by fever, palpitation and shortness of breath Extensive episodes of blood destruction are accompanied by violent abdominal pain and vomiting Once severe jaundice and anemia have developed, complete spontaneous remission is unusual. The jaundice is not accompanied by itching of the skin.

The symptoms of *cholelithiasis* are common Cholelithiasis is present in one half or more of these patients

EXAMINATION The *spleen* is enlarged During latent periods of the disease the spleen may be difficult to palpate. The enlarged spleen may attract attention by

producing a sense of oppression or weight, due to its size, or it may be the site of a sudden attack of pain. The *liver* is often slightly enlarged.

Chronic leg ulcer may be present over the internal or external malleoli.

The *tower skull* (*Turmschädel*) *is perhaps the commonest skeletal* anomaly. Other developmental anomalies may be present The changes in the bones demonstrable by roentgenologic examination are similar to those observed in sickle cell anemia and erythroblastic anemia

The fragility of the red corpuscles in hypotonic saline solutions is increased The anemia is of moderate degree or is absent A rapid fall to as few as 1,000,000 erythrocytes per cubic millimeter of blood may occur during one hemolytic crisis Reticulocytes are increased in number Polychromatophilia, normoblasts and microblasts are present The leukocyte count is normal, except during a hemolytic crisis when there is leukocytosis and a shift to the left

In the presence of deep jaundice the hemoglobin cannot be accurately determined The van den Bergh reaction is indirect, sometimes biphasic.

The urine contains increased amounts of urobilinogen, urobilin and coproporphyrin The stools contain bile pigment as well as excessive quantities of urobilin. The bone marrow obtained by sternal puncture reveals erythropoietic hyperplasia of the normoblastic type

False positive serologic reactions for syphilis may be revealed in congenital hemolytic jaundice They usually disappear following splenectomy.

DIAGNOSIS The combination of increased fragility of erythrocytes, hemolytic *anemia, reticulocytosis, spherocytosis, splenomegaly and jaundice and often* gallstones is diagnostic Gallbladder disease with gallstone in relatively young persons is suggestive of congenital hemolytic jaundice in whites and sickle cell anemia in Negroes.

Death may occur during a hemolytic crisis. Many patients, however, attain an advanced age despite the chronic anemia. A prolonged spontaneous improvement without jaundice may last until late adult life Once jaundice has supervened, it does not clear up until the spleen has been removed

Hemolytic Jaundice in Adults. There is *little* justification *for considering the* acquired form of hemolytic jaundice as a distinct clinical entity These patients are probably manifesting the same disease as that designated as congenital hemolytic jaundice, for in these patients there is a latent inherent defect in the erythrocytes permitting easy hemolysis, which awaits some infectious, toxic or *metabolic disturbance* to make the defect apparent

The acquired hemolytic jaundice comprises those forms which seem to be identical with the congenital form of the disease, with the exceptions of those which are secondary to some such disease as syphilis, tuberculosis, septicemia, leukemia, Hodgkin's disease, and cirrhosis of the liver If recovery from the primary disease should occur, the hemolytic jaundice disappears

The symptoms may be the same as those of the congenital form, namely, a progressive anemia, or a sudden onset with fever, prostration, abdominal pain, jaundice and anemia The hemolytic crises are more frequent and more severe. The anemia and pallor are more pronounced than the jaundice

The *symptoms* vary from those of a rapidly developing and fatal disease to those of a chronic disorder. In some instances in which the clinical symptoms resemble those of the congenital disorder, not only is the family history negative but examination of the blood of various members of the family reveals no evidence of a familial disorder

On examination the skin is pale and slightly jaundiced The spleen is enlarged There is spherocytosis Increased fragility of the erythrocytes is less common than in congenital hemolytic jaundice and may be present in but slight degree or not

at all. There are reticulocytosis and leukocytosis just the same as in the congenital form of the disease.

The diagnosis is based on the preceding blood findings. When the diagnosis is made, splenectomy should be performed

ACQUIRED HEMOLYTIC ANEMIA

The hemolytic diseases of congenital or hereditary origin were described in the pages immediately preceding this discussion In these diseases there is some inherent defect in the constitution, or in the maintenance of the erythrocytes.

In all forms of hemolytic anemia the changes present in the blood and bone marrow in either the acute or chronic forms represent the products of destruction of blood and its effects on the stimulation of the marrow and the tissues responsible for the removal of the residua of hemolysis Splenomegaly and demonstrable abnormalities in bone structure, the effects of long-continued overactivity of the spleen and bone marrow, are regularly present

In the more acute stages of hemolytic anemia there is an excessive destruction of erythrocytes, and anemia of varying degrees ensues Jaundice is a regular manifestation when there has been a sufficient hemolysis to liberate adequate amounts of pigment, and likewise, if there is excessive destruction, hemoglobinuria is present. If the bone marrow is normal, there is evidence of erythrocytic regeneration and leukocytosis.

There are many different kinds of hemolytic agents to cause acute and chronic hemolytic anemias These agents are the same as those listed as the cause of jaundice (see Jaundice, Chapter 13)

A common cause of acute hemolytic anemia in tropical and subtropical climates is malaria. The anemia is due to the destruction of red corpuscles by the plasmodium and to the toxic inhibition of the bone marrow activity The severity of the anemia may be partially correlated with the intensity and duration of the infection

Blackwater fever (black urine, hemoglobinuric fever, hemorrhagic malarial fever, black jaundice, canebrake yellow fever) is the result of chronic malarial infection for which the patient has been inadequately treated with quinine (see p 1291)

Bartonella bacilliformis causes a severe, acute hemolytic anemia.

The *bacterial toxins* from organisms *Clostridium perfringens, Streptococcus hemolyticus* and *Streptococcus viridans* may cause a profound hemolytic anemia which develops so rapidly that in a few days the erythrocyte count is less than 1,000,000 cells per cubic millimeter

The mechanism of the actions of *chemical agents* in the production of the anemia is obscure (see Chapter 19)

Acetanilid or *phenacetin* poisoning, usually obtained from headache medicine, is characterized by cyanosis, anemia, and loss of weight The cyanosis may be due to the formation of methemoglobin or other pigments (paramidophenol derivatives).

When there is an *idiosyncrasy to sulfanilamide*, anemia may appear between 24 and 72 hours after the first administration of the drug The anemia is likely to recur if the drug is administered again The destruction of blood is rapid and is accompanied by fever, jaundice, marked leukocytosis, reticulocytosis and normoblasts

Vegetable poisons are agents in production of hemolytic anemia Inhalation from bean plants (*Vicia faba*) when in blossom or ingestion of fava beans when fresh, causes in sensitive persons an acute hemolytic anemia, favism. The castor bean contains the hemolytic agent, ricin (see p 20)

Among *animal poisons* venom from the pit vipers (rattlesnakes, moccasins and copperheads) of the United States contains a lecithinase which converts lecithin to *lysolecithin*, a powerful hemolytic agent (see p. 1446)

Endogenous hemolysins are formed from the actual heating of the blood following severe burns and sunstroke Hemolysis of the blood is often severe in fatal sunstroke (see p 1477)

Hemolysins of the immune-body type may produce hemolytic anemia and hemoglobinuria. The anti-Rh agglutinins are formed after repeated blood transfusions. In

rare instances the anti-M and anti-P agglutinins also are the cause of *intragroup hemolytic reactions to transfusion.* The iso-immunization of the Rh-negative woman by her Rh-positive fetus, rendering her susceptible to transfusion reactions and producing in the fetus a fulminating and often fatal hemolytic anemia (*erythroblastosis fetalis*), is a recent subject of much conversation (see Transfusion Reactions, p. 795)

There are the cold hemagglutinins In paroxysmal hemoglobinuria e frigore a hemolysin activated by cold is present In nocturnal hemoglobinuria hemolysis depends on an immunologic system. In certain cases of acute hemolytic anemia heat labile autohemolysins requiring complement have been demonstrated.

SYMPTOMS A rapid destruction of blood is manifested by severe pain in the back, abdomen or legs, headache, and chill Synchronous with the chill is fever which rapidly subsides If destruction of blood is excessive, profound prostration and shock ensue. Abdominal pain and melena are common. This is the syndrome of acute hemolysis or hemolytic crisis.

Anuria or oliguria may develop The urine is dark as the jaundice develops. Anemia, weakness and palpitation occur in rapid succession. Reactions to transfusion are common

EXAMINATION The findings in the syndrome of acute hemolytic crisis are well illustrated by paroxysmal hemoglobinuria and hemoglobinemia. Vascular disturbances characterized by vasoconstriction are present. Thrombosis and gangrene may be observed Infarcts in the spleen and the lungs are manifested by enlarged spleens, consolidated areas in the lungs and hemiplegias Thrombosis of the arteries and veins of the extremities may be observed

A rapid destruction of blood liberates hemoglobin in the blood plasma. The van den Bergh reaction is indirect and the concentration of serum bilirubin is increased. The intensity of bilirubinemia depends on the extent of destruction of blood and on the capacity of the liver to remove the pigment from the blood stream and excrete it in the bile If hemolysis is severe, hemoglobinemia ensues Hemoglobin, when once present in the urine, persists until the plasma concentration is decreased to 30 to 50 mg. per 100 ml

Pigments other than hemoglobin may appear in the blood plasma Hemoglobinemia and methemalbuminemia invariably are associated with bilirubinemia When the destruction of blood is less rapid, only bilirubinemia is present

The urine contains albumin and granular and red cell casts

There are signs of active erythrocytic regeneration Reticulocytes are increased in number There are polychromatophilia and numerous normoblasts and macroblasts

Microcytes, which show no central pallor when stained, are characteristic of familial hemolytic jaundice.

In this disease the *fragility of the erythrocytes,* when suspended in hypotonic solutions of sodium chloride, is greatly increased Increased fragility in hypotonic saline solutions is unusual in other forms of hemolytic anemia.

There are leukocytosis and a shift to the left, and myelocytes and even myeloblasts may be present Platelets are numerous and large. The bone marrow is hyperplastic.

DIAGNOSIS The diagnosis depends on the history and findings as enumerated

Chronic Hemolytic Anemia. Chronic hemolytic anemia is manifested by jaundice (see Chapter 13).

NORMOCYTIC ANEMIA

In normocytic anemia the erythrocyte maintains its normal size, shape and color.

The causes of normocytic anemias may be divided into two large categories: (1) sudden loss of blood from hemorrhage and (2) decreased blood formation

The causes of *sudden losses of blood* are numerous and often obvious, but in some instances the cause is indeterminable.

The *rapid loss of 2 liters of blood* may cause immediate death, whereas this amount, or even more, of blood lost over a 24-hour period may be tolerated

The immediate cause for *decreased formation* is failure of bone marrow to produce, as when it becomes replaced with fat or becomes inactive from any cause The commonest cause of marrow inactivity is the toxic effects from infection and exhaustion during the course of chronic disease In some instances blood formation is hindered by infiltration of marrow with neoplastic growths There are both relative and absolute normocytic anemias A relative normocytic anemia is produced by an increase in the amount of plasma, an hydremia, without alteration in the total quantity of erythrocytes In contrast with the hydremic state is the concentration of normocytes in dehydration.

SYMPTOMS. When the loss of blood has been moderate (500 ml), unless the patient rises or attempts to walk there are no symptoms On the patient's arising, the pulse rate accelerates and the blood pressure tends to fall The feeling of weakness and dyspnea occur only on physical exertion

When more than 500 ml of blood is lost, on sitting up faintness and syncope, accompanied by bradycardia, may ensue A loss of large amounts of blood causes shock (see p. 792)

The severity of the hemorrhage cannot be determined during the first symptoms of loss of blood because vasoconstriction accompanied by a continuing dilution of the blood by body fluids passing into the vessels produces constantly changing values. In rare instances hemorrhage into the intestinal tract is followed by digestion of blood, and the concentration of urea nitrogen in the blood may increase However, in practice this is rare Hemorrhage into one of the body cavities or into a cyst followed by reabsorption of the products of hemoglobin may produce jaundice. Moderate fever may accompany gastrointestinal hemorrhage High fever occurs when there is escape of blood into muscles, parenchymatous organs or body cavities.

EXAMINATION Within the first hour after a hemorrhage there are an increase in the platelet count and a shortening of the coagulation time. Within 5 or 6 hours polymorphonuclear leukocytosis is present (10,000 to 20,000 per cubic millimeter) There is a shift to the left in the myeloid series, and myelocytes make their appearance. Reticulocytes begin to increase within 24 to 48 hours The maximal number (5 to 15 per cent or higher) is reached within a week

The erythrocyte count and the value for hemoglobin are high and then decrease. Normoblasts and polychromatophilia appear after several days if the hemorrhage has been severe The value for the hemoglobin content is the most valuable and the most practical to obtain Continued bleeding is suggested by high count of reticulocytes and leukocytes continuing after the first week subsequent to the hemorrhage

In the healthy person blood regeneration is rapid and the hemoglobin reaches normal limits after 6 to 8 weeks, even after severe hemorrhages.

DIAGNOSIS An anemia is diagnosed when the values for the hemoglobin and the total erythrocyte count are less than normal A severe anemia, when the cause is not obvious, before the age of 50 years, usually originates in the alimentary tract in men and in the genital organs in women

Anemias of Decreased Blood Formation. There may be a decreased blood formation in cachexias, infections with or without fever, nutritional deficiency, aplastic anemia from any cause, and an invasion of the bone marrow by malignant tissues, producing the so-called myelophthisic anemias Finally, there are anemias arising from decrease or lack of blood formation when the marrow is hyperplastic The reason for this origin of anemia is unknown.

Aplastic Anemias. These anemias are designated progressive hypocythemia, aregeneratory anemia, aleukia haemorrhagica, panmyelophthisis, hypoplastic anemia, and toxic paralytic anemia

Aplastic anemias are of two types, primary and secondary.

Primary Aplastic or Refractory Anemia. This is a severe anemia accompanied by granulocytopenia and thrombocytopenia which will not respond to any treatment except the transfusion of whole blood. Anemia of this type is not the result of infection, chronic renal or hepatic disease, malignant disease, malnutrition, or physical or chemical agent It results from either inborn or acquired endogenous factors. In the young patient there may be present increased pigmentation of the skin, hypoplasias of the gonads, and other developmental anomalies. The disease in the young person has been termed *idiopathic aplastic anemia.*

There is bleeding from the mucous membrane, pharynx and gums. The hemorrhage depends in part on the degree of granulocytopenia and thrombocytopenia If the progress is slow, there may be only progressive weakness and fatigability. If the disease progresses rapidly, there are high fever and anoxemia When the anemia becomes well established, there are bleeding from the nose, mouth, or gastrointestinal tract, menorrhagia and purpura.

There may be purpuric spots in the skin There is pallor of the skin and mucous membranes. Retinal hemorrhages are often present The spleen is not palpable In those in whom the bone marrow is hyperplastic the circulating blood reveals no signs of regeneration. The erythrocyte count is often as low as 2,000,000 and the leukocyte count 1,500 per cubic millimeter There are leukopenia and thrombocytopenia. An absolute lymphocytopenia is present, for the monocytic and granulocytic series of cells are gone The coagulation time is normal The bleeding time is prolonged and the blood clot retracts poorly

The diagnosis is based on the presence of anemia, leukopenia and thrombocytopenia In differential diagnosis it is necessary to consider aleukemic leukemia. Idiopathic aplastic anemia in time proves fatal despite blood transfusions

Secondary Aplastic Anemia Due to a Chemical or a Physical Agent. A secondary aplastic or refractory anemia may follow the administration of or the exposure to certain chemical or physical agents (see Chapter 19)

Simple Chronic Anemia (Secondary Anemia). A simple chronic anemia is associated with the majority of infections It is often insidious in its inception and frequently responds slowly to treatment. It is often a normocytic anemia.

The name chronic secondary anemia has been and still is employed for this type of anemia Hematologists object to the use of this term because of the fact that any anemia from any cause is secondary

A simple chronic or secondary anemia occurs in most instances of subacute and chronic inflammatory disease For instance, osteomyelitis, chronic ulcerative colitis, ileitis, pelvic inflammatory disease, infections of the urinary tract, bronchiectasis and pulmonary abscess often are associated with a simple chronic anemia About two thirds of those who have a subacute *Streptococcus viridans* endocarditis have an anemia which may be severe

Anemia is almost always coexistent with nitrogen retention It may be present in an acute or a chronic nephritis when there is no increase in the concentration of urea nitrogen in the blood Anemia is not related to the type of renal disease. It may occur in acute or chronic nephritis, in congenital cystic renal disease, or in urinary retention In an acute urinary retention, without an increase in the concentration of blood urea in the beginning, for instance, from an enlarged prostate, if there is an anemia, it is suggestive of some disease other than benign prostatic enlargement

Infestation by *parasites*, with the exception of hookworm infestation, usually does not cause anemia Anemia in hookworm infestation, when present, probably is the result of chronic loss of blood When anemia is encountered in amebiasis, the cause is nutritional disturbance, loss of blood, or secondary infection In infestation with *Schistosoma mansoni* there may be hypochromic microcytic anemia in the intestinal phase or macrocytic anemia when cirrhosis of the liver develops. Anemia in malaria is hemolytic in origin and is considered with the hemolytic anemias

Aberrations in *intestinal absorption* are rarely responsible for the development of anemia in intestinal disorders accompanied by diarrhea If anemia develops in these disorders, its origin is from intestinal bleeding which almost always is present. For instance, a patient may have a functional disorder characterized by a diarrhea for years and not become anemic.

Nutritional deficiency may produce macrocytic anemia, hypochromic microcytic anemia and perhaps normocytic anemia The importance of the lack of any particular vitamin in the production of anemia is not known except for vitamin B_{12} deficiency (see Pernicious Anemia, p 844)

Anemia of the so-called physiologic variety is common in *pregnancy* This type of anemia may be present by the eighth week and may progress until about the twenty-second week and then become stationary Even in this anemia a reduction in hemoglobin to less than 10 gm per 100 ml of blood is worthy of concern. In the puerperium the erythrocyte count and volume of packed red cells increase rapidly, but the hemoglobin returns to within normal limits more slowly

Malignant disease does not directly cause anemia through the action of toxins or hypothetic substances. Malignant disease in the alimentary tract often causes anemia through loss of appetite as the result of interference with digestion and absorption, or because of loss of blood If chronic loss of blood is sufficient, hypochromic microcytic anemia ensues When metastasis occurs, and the bone marrow is involved, myelophthisic anemia is characteristically present

Simple chronic or secondary anemias of mild degree are usually symptomless. Any symptoms present are those of the primary disease. In severe grades of anemia the symptoms are in accord with the rapidity of development A patient may have a severe anemia with few or no symptoms if the anemia has developed slowly over a period of months or years

There may be pallor from confinement or from anemia. Skin pallor alone or combined with pallor of mucous membranes is not a good criterion for the presence of anemia

The reduction in the number of erythrocytes, the quantity of hemoglobin, and the volume of packed red cells corresponding in degree are the indications of anemia

The diagnosis of a simple chronic (secondary) anemia is based on a reduction below normal of the erythrocytes (5,000,000 for men and 4,500,000 for women) and the hemoglobin (below 14 gm. per 100 ml of blood for men, and 12 gm for women) In the normocytic anemias the volume of the packed cells is decreased in direct proportion to their [illegible]

Myelophthisic Anem [illegible]

of anemia associated with [illegible] of the conditions thus designated are erythroleukemia, aleukemic leukemia, leukemia with osteosclerosis, leukoerythroblastosis, megakaryocytic myelosis, osteosclerotic anemia, aleukemic megakaryocytic myelosis, myeloid megakaryocytic hepatosplenomegaly, chronic nonleukemic myelosis and agnogenic myeloid metaplasia

Metastatic carcinoma in bone marrow is perhaps the commonest cause of this type of anemia *Multiple myeloma* causes an occasional case In very rare instances a myelophthisic anemia is caused by *myelosclerosis* (osteosclerosis myelofibrosis) or by osteopathia condensans disseminata, in which there is an irregular increase of fibrous or bony tissue in the bone marrow Myelophthisic anemia may occur in a hereditary disorder known as *marble bones* (ivory [illegible]

A myelophthisic anemia is encoun[illegible] *xanthomatoses,* Gaucher's disease, [illegible] osteitis deformans, osteitis fibrosa cystica, osteomalacia, osteogenesis imperfecta cystica, in *poisoning* by fluorine or phosphorus, and after prolonged administrations of anterior pituitary extract, parathyroid extract, estrogens and irradiated ergosterol and in hyperparathyroidism

Deep bone pains, abdominal pain, epistaxis, loss of weight and weakness are

common symptoms. There may be palpitation, dyspnea or purpura. The symptoms may be such as to suggest the underlying disease.

Splenomegaly may be the only finding on examination except the anemia There may be tenderness along the long bones, Bence Jones protein in the urine, and rouleaux formation of the red cells in the smears. The total amount of serum protein is increased An anemia exists in variable degree characterized by the presence of normoblasts in the circulating blood in numbers out of proportion to the severity of anemia Reticulocytes are increased, and polychromatophilia and stippling may be present

The total and differential counts of cells of the myeloid series maintain their normal proportions. Variable numbers of myelocytes and myeloblasts may be present The platelet count may be normal or moderately reduced, or in some a thrombocytopenia may be present.

Myelophthisic anemia is suspected whenever nucleated erythrocytes or myelocytes are observed in the circulating blood in those who have little anemia. A myelophthisic anemia is suspected if the total serum protein exceeds 8 gm. per 100 ml, if Bence Jones protein is found in the urine, or if rouleaux formation of the erythrocytes is observed in the blood smears. The diagnosis depends on positive evidence of distortion of bone architecture by means of roentgenologic examination in association with the foregoing enumerated blood findings

PERNICIOUS ANEMIA AND OTHER MACROCYTIC ANEMIAS

Pernicious Anemia. Pernicious anemia is called also Addison's anemia, Biermer's anemia, Addison-Biermer anemia, and Biermer-Ehrlich anemia

Castle has recently concluded that the information presently available suggests that addisonian pernicious anemia is the clinical result of a deficiency chiefly of vitamin B_{12} This deficiency is predominantly due to a lack of gastric secretion, itself usually a manifestation of hereditary predisposition and of advancing age In some patients local disease or surgical ablation destroys this essential function of the stomach The consequent failure of vitamin B_{12} to be assimilated affects hematopoiesis adversely and frequently also the integrity of the alimentary tract and of the nervous system The proximal cause of the macrocytic anemia is both decreased production and increased destruction of defective red cells Either both processes must be of only moderate degree, or the magnitude of each must be inversely related to that of the other

Defective diets and intestinal dysfunction or disease, especially when gastric secretion is not significantly disturbed, may result in nutritional macrocytic anemia in which the predominant deficiency is not of vitamin B_{12} but of pteroylglutamic acid Dietary deficiency of ascorbic acid probably restricts the formation of the metabolically active and closely related form of pteroylglutamic acid known as the citrovorum factor, or folinic acid. Vitamin B_{12}, pteroylglutamic acid and ascorbic acid are apparently required for normal hematopoiesis

Pernicious anemia affects chiefly, but not exclusively, the white race. Racial and hereditary influences appear to be of chief importance in its incidence and distribution The inherited feature of the disease is manifested by achylia gastrica. Achlorhydria is not the essential factor, but its presence is necessary for the diagnosis Achlorhydria is present in many who do not have pernicious anemia

The disease has been described in single ovum twins. Pernicious anemia has occurred in the men, and chronic hypochromic anemia in the women of some families

Men and women are affected equally The disease is rare in persons less than 20 years old. The greatest incidence is after 40 years of age.

Those who have pernicious anemia may appear to be of the same constitutional

type. They are often short and have a deep short thorax, blue or light-colored eyes, and gray or white, fine-textured hair which has lost color prematurely

Pernicious anemia is often associated with infections and arteriosclerosis, which tend to impair the response to liver therapy It may be associated with diabetes mellitus, which has in common with pernicious anemia atrophy of the mucous membrane of the tongue, diarrhea, and neurologic disturbances Any condition which destroys the absorptive portions of the stomach, such as carcinoma or total or subtotal gastric resection, may cause anemia having many of the characteristics of pernicious anemia Rigler and Kaplan report in a series of necropsies (22,231) at the University of Minnesota on subjects 45 or more years of age that evidence of pernicious anemia was discovered in 293 In 36 of these there was carcinoma of the stomach. This incidence of carcinoma of the stomach was more than three times greater than the normal morbidity rate for carcinoma of the stomach The Minnesota investigators found that 12 per cent of the deceased patients who had pernicious anemia had carcinoma of the stomach, and 7 1 per cent had benign polyps.

Symptoms Often the initial symptoms are general weakness, sore tongue, and numbness or tingling of the extremities Commonly the patient complains of faintness, stiffness of the legs and difficulty in walking, headache, nausea, lack of appetite, vomiting, dizziness, shortness of breath, palpitation, loss of weight, pallor, abdominal pain, diarrhea and sore tongue

Soreness and a burning sensation affect the anterior half of the tongue The glossitis may appear before there is a known anemia, or it may portend a relapse and thus indicate inadequate treatment

Diarrhea occurs but is not common It is doubtful that achlorhydria is ever responsible for such a diarrhea The other complaints referred to the gastrointestinal tract are inconstant They are anorexia, nausea, "gas," a sense of fullness in the epigastrium, heartburn, vomiting, and irregular but usually not intense abdominal pain unless a visceral crisis secondary to the changes in the spinal cord occurs.

In those who have a severe anemia, congestive heart failure may ensue However, degenerative cardiac disease is not often due to pernicious anemia It is usually due to degenerative vascular changes occurring in the age group affected by this anemia. When vascular symptoms, such as those of intermittent claudication, result from pernicious anemia, relief follows adequate treatment and maintenance therapy. Cardiac symptoms occur because, during anemia, the circulation time is shortened as the result of increased heart rate and there is a greater output per beat and consequently the amount of work done by the heart per minute is increased. In the presence of greatly decreased concentration of hemoglobin angina pectoris, alone or accompanied by congestive failure, may develop These cardiac ailments are precipitated by oxygen want, for there is not enough hemoglobin to carry sufficient oxygen to supply the tissues

In the presence of severe anemia fever is present which disappears as the anemia is relieved

Complaints referable to the nervous system are present in 9 of every 10 patients who have pernicious anemia

The symptoms referable to the nervous system may occur while anemia is mild or even absent There may be irritability, lack of concentrating power, dullness, drowsiness, and depression If there are changes in the spinal cord, pyelitis and cystitis are frequent complications due to an inability to empty the bladder.

The special senses may be disturbed by, for instance, tinnitus, visual defects and retinal hemorrhages Optic atrophy is rarely observed and, like the symptoms of combined sclerosis of the spinal cord, it may be the first symptom

EXAMINATION. The loss of body weight is slight. Often the *skin* is smooth and inelastic. When the anemia is severe, the skin is dry, and is yellowish, as are the scleras. There may be diffuse or blotchy brownish pigmentation and large areas of leukoderma over the dry smooth skin.

The epithelium of the tongue is devoid of circumvallate papillae. Atrophy of these papillae is characteristic, and papillae which have atrophied for any reason do not return to normal size under treatment. Smooth, glazed-appearing tongues are most frequently observed in those of advancing years; such a tongue is not indicative of pernicious anemia

As the result of the anemia a fever, temperature up to 100 F, may occur which disappears promptly after effective treatment

Cardiac murmurs are often heard and occasionally there is a diastolic murmur at the aortic area. The vessels in the neck pulsate if the anemia is severe, and venous hums may be present. The blood pressure is commonly low in pernicious anemia

The liver is often detectably enlarged. When there is congestive heart failure in association with the anemia, the liver may be greatly enlarged and tender. The spleen is moderately increased in size before treatment and during relapses A very large spleen is unusual. With adequate treatment the liver and spleen return to their normal sizes

Significant findings on examination are bilateral diminution or loss of vibratory sensation over the tibias and bones of the arms and in-co-ordination in the lower extremities In-co-ordination, resulting in disturbance of gait, may be more severe on one side than on the other The fingers often lose the power to perform synchronized movements. These signs indicate a combined sclerosis of both the posterior and the lateral funiculi and involvement of peripheral nerves. The peripheral nerve degeneration accounts for the hyperesthesia of the soles of the feet

Examination of the blood reveals macrocytes filled with hemoglobin, irrespective of size and shape, which are characteristic of pernicious anemia The greater the anemia, the more macrocytes are present in the blood. The macrocytes may be circular or oval and may have a diffuse basophilia

In the blood of those who have advanced pernicious anemia all the abnormalities of prematurity of erythrocytes except hypochromia may be present There may be a punctate basophilia, chromatin particles (Howell-Jolly bodies), acidophilic rings of various shapes (Cabot's rings), and nucleated erythrocytes The cytoplasm of the nucleated erythrocytes may be acidophilic, polychromatic or basophilic.

The erythrocytic diameters are estimated by the *mean corpuscular volume.* When the anemia is slight or moderate, values of 95 to 110 cubic microns are common (normal 82 to 92 cubic microns). When the anemia is more severe, the mean corpuscular volume may reach 150 cubic microns. The volume index and the color index are increased.

The erythrocytes in pernicious anemia are not supersaturated with hemoglobin The increased corpuscular size accounts for the increased amount of hemoglobin in pernicious anemia The erythrocyte count is often found to be lower than the appearance of the patient suggests

The *iron content of the serum* is abnormally high. The blood *plasma* is yellow in pernicious anemia The van den Bergh reaction is indirect and the quantity of serum bilirubin is increased, owing to hemolysis, which is characteristic of the disease

Achlorhydria is present. The diagnosis of pernicious anemia should not be made unless there is achlorhydria manifested by a *failure to secrete free hydrochloric acid* after ingestion of a test meal, or even after the subcutaneous injection of histamine (0 005 mg per kilogram of body weight).

During relapse the urobilinogen and urobilin are increased in the *urine* to several times their normal values

The leukocyte count is often low, and there may be relative lymphocytosis and hypersegmented neutrophilic leukocytes. Eosinophilia may be present.

DIAGNOSIS A sore tongue, numbness, tingling, and weakness of the legs, associated with the presence of a macrocytic anemia and achlorhydria, are diagnostic.

If a macrocytic anemia is revealed, it will then be realized that the color index is increased. The smear may reveal large, well-filled red corpuscles and misshapen red cells (poikilocytosis), a punctate basophilia (Howell-Jolly bodies), or rings (Cabot's rings), and occasionally nucleated erythrocytes (macroblasts and megaloblasts). If a competent cytologist does not see the blood smears, and free hydrochloric acid is absent from the gastric contents, a therapeutic test by administration of liver extract may be diagnostically useful A favorable response favors the diagnosis of pernicious anemia but is not conclusive. The administration of a potent liver extract, if the patient has pernicious anemia, is followed in several days by a characteristic reticulocyte response and rapid relief of symptoms, as well as a rise in the erythrocyte count unless there is some complicating disease. If the parenteral administration of a liver extract of known potency is not followed within 10 to 14 days by definite signs of response, the diagnosis of pernicious anemia must not be made. It may be impossible to make a diagnosis of pernicious anemia in patients who fail to respond to treatment, or in patients who have received treatment. The only time a definite diagnosis can be made after a patient who has received liver for the treatment of pernicious anemia has not responded is when there is free hydrochloric acid in the gastric contents. If there is free hydrochloric acid in the gastric contents, the patient does not have and did not have pernicious anemia

In those who have crippling neurologic disorders (a combined sclerosis) and secondary infection, death is not preventable. In all others the prognosis is good if adequate liver therapy is maintained

Macrocytic Anemia Associated With Sprue, Nontropical Sprue, Idiopathic Steatorrhea and Celiac Disease. These conditions are all considered in Chapter 22

Macrocytic Anemia and Digestive Disease. A macrocytic anemia may occur in those having carcinoma or polyposis of the stomach who do not have pernicious anemia It may occur after partial gastrectomy In relation to the number of such operations which have been performed, the incidence of macrocytic anemia following these operations is small Hypochromic anemia is of common occurrence in gastrectomized individuals

Patients who have intestinal strictures and enteroenterostomies, gastroenterostomies, enterocolostomies, or gastrojejunocolic fistula or gastrocolic fistula and extensive ileitis, may have macrocytic anemia

Progressive weakness and loss of weight are always present and a few patients have glossitis However, manifestations of disease of the nervous system similar to those present in pernicious anemia are absent in these intestinal macrocytic anemias

The physical examination reveals loss of weight, weakness and often tenderness of the abdomen Examination of the blood reveals findings seemingly identical with those of pernicious anemia in regard both to morphology and to degree of reduction in the erythrocyte count In one half of these patients analysis of gastric *contents* reveals free hydrochloric acid, a finding which immediately eliminates pernicious anemia

Macrocytic Anemia in Diseases of the Liver. *Macrocytic* anemia may be associated with disease of the liver. The anemia resembles that seen in pernicious anemia although it is rarely as severe.

In severe hepatic disease the macrocytic anemia may be the result of defective storage or metabolism of the *antianemic principle*. In a patient who has hepatic disease which may accompany chronic alcoholism, the macrocytic anemia may be

the result of a dietary deficiency state, for in some chronic alcoholics faulty absorption is evident. In others increased destruction of blood is etiologically obvious and important.

Infestation With Diphyllobothrium latum (Fish Tapeworm) It has been said that persons infested with fish tapeworm (*Diphyllobothrium latum*) may have signs and symptoms resembling in all respects those of pernicious anemia, including such symptoms as glossitis, diarrhea, paresthesias and ataxia, as well as the classic blood findings

Macrocytic anemia is rarely encountered, however, when there is infestation with the fish tapeworm The evidence strongly suggests that anemia in association with fish tapeworm infestation is in many instances a matter of coincidence. In cases in which the anemia is relieved after removal of the parasite it is possible that the tapeworm acts in some way to precipitate anemia in a constitutionally predisposed individual.

Macrocytic Anemia and Endocrine Disease. A yellowish pallor of the skin associated with anemia is common in hypothyroidism The anemia of myxedema is rarely severe and is usually normocytic or macrocytic, or it may be hypochromic. Pernicious anemia and myxedema may occur in the same individual, and the presence of hypothyroidism may inhibit the response to liver therapy. The erythrocytes are uniformly larger than normal cells. There is no poikilocytosis or evidence of active blood regeneration. The administration of thyroid is followed by a very slow restoration of the blood to normal

Achrestic Anemia. Achrestic anemia is a rare form of macrocytic anemia which is characterized by a chronic but progressive and often fatal course, and responds temporarily, or not at all, to liver therapy. The morbid anatomy resembles that of pernicious anemia

MICROCYTIC ANEMIA

(Iron Deficiency Anemia)

This type of anemia is known also as nutritional hypochromic anemia, chronic or idiopathic hypochromic anemia, and chlorosis

The term hypochromic indicates that the concentration of hemoglobin of the erythrocytes is quantitatively reduced, both from the reduced size of the cell and *from the reduced amount of hemoglobin contained therein* The concentration of iron in the serum is decreased in iron deficiency anemia. The term hypochromic microcytic anemia indicates iron deficiency except when the patient has Mediterranean anemia

The causative factors operative in the production of iron deficiency are chronic loss of blood, disorders of the alimentary tract which may be due to an inadequate diet, or the result of chronic diarrhea, hookworm disease or perhaps achlorhydria

Hypochromic anemia is observed in association with bleeding from the uterus (menorrhagia and metrorrhagia), peptic ulcer, bleeding hemorrhoids, carcinoma of the stomach or colon, ulcerative colitis or ileitis, bleeding varices and severe epistaxis or repeated hemoptysis It is frequently seen in multiple hereditary telangiectasia and may be found in chronic thrombocytopenic purpura Iron deficiency anemia occurs most frequently in women

Chlorosis. The name chlorosis formerly was used to designate the anemia of young women. The term arose from the greenish yellow color of the affected girls Anemia occurring in girls and young women, when it results from dietary deficiencies, is usually mild If it is accompanied by menorrhagia, it may be severe

There is a chronic microcytic anemia which occurs in women in the third to fifth decades of life which is similar in many respects to chlorosis This anemia has been ... *chlorosis*, and essential,

... is, for in a family there

may have been hypochromic microcytic anemia in the women, and one or more of the men of the family may have had pernicious anemia

Hypochromic microcytic anemia more frequently affects white persons, but it is observed in Negroes. In many instances it is associated with achlorhydria and it is more common and more pronounced in the poor than in the prosperous

The history almost always includes rapidly repeated gestation with excessive loss of blood, an inadequate convalescence following illnesses or gestation, or both Menstrual disturbances, often menorrhagia, are common

Many women who have hypochromic anemia in pregnancy are found to have been anemic before. The hydremia of pregnancy often accentuates an already existent anemia

SYMPTOMS. The first symptoms are weakness, fatigability, and often pallor. The nervous irritability, inability of mental effort, headache, dyspareunia, and disturbances of sleep do not arise from the effects of the anemia Likewise the anemia cannot be held responsible for the lack of attraction which these women have for members of the male sex

The judgment and appetite are capricious, manifested by abnormal cravings for unusual articles of food Aerophagia, heartburn and epigastric distress are common, but no commoner than constipation or diarrhea Difficulty in swallowing, *sore tongue, or sore mouth*, is often present

Palpitation, dyspnea on exertion, and choking sensations and inability to take a deep breath are common complaints Sighing respirations may be an objective symptom. Starting on beginning to sleep is common and may be interpreted by some of these women as heart trouble

Neuromuscular pains, vasomotor disturbances, numbness and tingling are common in those who have an iron deficiency anemia, but these complaints cannot be considered peculiar to anemia of this kind

EXAMINATION Many of these women are carefully and attractively dressed and through make-up attain the appearance of good physical health They are often gracious and gentle in social intercourse A few are pale, tired and lifeless. The mucous membranes, nail beds and conjunctivae may be pale The skin over the body may be inelastic and dry The skin of the face and hands has a softness and an elastic appearance purely from the effects of cold creams and olive oil The hair is dead in appearance and is often scanty A greenish yellow tint to the skin described by early physicians is rarely observed nowadays. This skin coloration is more commonly seen in young men at the present time and in them it is of a hereditary origin

Papillary atrophy of the tongue may be present Comparable degrees of papillary atrophy, however, occur in those who are not anemic These patients have, and often complain of, a dry mouth Probably as the result of dryness, from a lack of desire for water, fissures occur at the angles of the mouth, and on the mucous membranes of the mouth are often small bullae surrounded by areas of erythema

Functional systolic cardiac murmurs are common The abdominal wall is atonic and inelastic The liver is often palpable, the spleen rarely so

In the blood there are microcytes and elongated poikilocytes. There may be some macrocytes and polychromatophils, which indicate a feeble effort to form hemoglobin-containing corpuscles Reticulocytes are normal and an occasional normoblast and microblast may be found. The hemoglobin is reduced out of proportion to the erythrocyte count and volume of packed red cells The erythrocyte count may be normal or even somewhat above normal when the hemoglobin is as low as 8 gm per 100 ml. of blood The platelets are usually normal in number and small The plasma protein content is often reduced. The leukocytes may be normal in number or slightly reduced Achlorhydria is a common finding. The bone marrow is hyperplastic and shows a relative as well as an absolute increase of normoblasts

DIAGNOSIS The diagnosis of hypochromic anemia is made by those who are accustomed to examining stained blood smears and is based on the presence of

decreased hemoglobin concentration and a decrease in the volume of the packed cells. In many instances it will be observed that the etiologic factors operating in the production of hypochromic microcytic anemia are apparently the same as those present in the production of a hyperchromic macrocytic anemia.

Relapses occur unless administration of iron is continued. This is true particularly in women before the climacteric.

The iron deficiency disease, *kasai*, occurs in the dark-skinned natives of tropical climates This is the same condition as the hypochromic microcytic anemia of the white races It is characterized by anemia, edema, digestive disturbances, and depigmentation of the skin However, the common form of depigmentation of the skin, vitiligo, is not due to an anemia (see Chapter 8)

POLYCYTHEMIA

Increases in the number of erythrocytes (more than 5,500,000 cells per cubic millimeter) may be absolute or permanent, as in polycythemia vera, or the increases may be relative or transient or permanent as in conditions of anoxia In either instance the increase in erythrocytes is termed erythremia or polycythemia.

Polycythemia Vera (Erythremia, Absolute Polycythemia) This disease is designated most commonly, in addition to the foregoing names, as Vaquez' disease, Osler's disease, polycythemia rubra, and cryptogenic polycythemia

The terms Gaisbock's syndrome and polycythemia hypertonica refer to the occurrence of polycythemia and hypertension without splenomegaly. In this condition there is moderate or marked arteriosclerosis and the heart is enlarged Apoplectic strokes are common. There is no good reason for distinguishing this syndrome.

The disease is said to be most frequent in Jews and rare in Negroes Some have thought that polycythemia vera or erythremia may have a familial tendency. The cause is unknown The age at onset of symptoms in most cases is in middle or late life

PATHOLOGY The spleen is enlarged, smooth, moderately hard, and may contain infarcts, thrombi and cysts The liver is often enlarged, hyperemic, and may be cirrhotic The bone marrow shows evidence of active hematopoiesis The blood flow is slowed as the result of increased viscosity of the blood and thus infarcts and thrombi are commonly present.

SYMPTOMS. The usual experience is that there are no symptoms which can be attributed to polycythemia. The symptoms are the common ones of weakness, headache, dizziness, ringing in the ears, and visual disturbances In the more advanced instances of the disease dyspnea and weakness are the chief complaints. Headache is a common complaint Vertigo and giddiness, transitory syncope, insomnia, weakness, a sensation of fullness in the head, and numbness and tingling in the fingers and in the feet are very common

Visual disturbances, including dimness of vision, sometimes temporary blindness, scotomata, specks and bright points in the field of vision, diplopia and temporary paralysis of one of the eye muscles, are frequent complaints All visual disturbances are usually increased on raising the head from a lowered position

Intercurrent infections are frequent, especially those of the respiratory tract Bronchitis and emphysema may develop In patients who have hypertension, particularly, chronic renal disease and arteriosclerosis are common

As the disease progresses, epistaxis, bleeding gums, and massive hemorrhages from varices in the esophagus, stomach or bowel, and respiratory passages, and hemorrhage into the peritoneal cavity and into the spleen may appear suddenly Thrombi in the mesenteric veins and arteries are not diagnosable as such. When thrombosis occurs, the symptoms are very much like those of a general peritonitis or the perforation of an ulcer. Dyspnea on exertion, cough and hoarseness are usual Respiratory infections are easily acquired by these patients.

Vascular lesions of the brain of sudden onset constitute the most frequent and

serious complication A paralysis may be the first symptom, less common are myoclonia, chorea, attacks of grand mal, and symptoms suggesting brain tumor, general paresis and tabes. Narcolepsy, attacks of catalepsy, and psychic disturbances of various types, including loss of memory, mental depression, confusion, hallucinations, and slurring of speech, may be associated with and caused by a polycythemia vera.

Pains in the legs are troublesome and severe Paresthesias and pruritus may be very troublesome Swelling and pain (erythromelalgia) in the extremities are common. Thrombosis is a common occurrence in arteries in every part of the body in polycythemia. The symptoms from the various and widely distributed thrombi may be perplexing

EXAMINATION. The color of the face, particularly of the lips, cheeks, tip of the nose, the ears, the neck, and also of the distal portions of the extremities, produces the characteristic appearance (rubor) of these patients The degree of red or blue and the sensitiveness to cold of the skin depend on the quantity of reduced hemoglobin present and thus on the severity of the disease.

Ecchymoses of various sizes are common, manifested as red or dark violet spots, or brownish pigmentation of the skin and mucous membranes. Hematomas may occur in any part of the body, and they are often present in the urinary bladder, vagina and perineal regions and cause pain on sitting and on urination Descriptions of the varied skin lesions include dry skin, eczema, acneform or urticarial changes, acne rosacea and even a nodular eruption similar to the specific infiltration found in leukemia.

The peripheral arteries are often markedly thickened The changes in these arteries may reproduce the findings present in an atherosclerosis in the peripheral vessels. Vascular accidents, coronary thrombosis, claudication without occlusion, arterial occlusion with gangrene, acroparesthesia, the Raynaud phenomenon and thromboangiitis obliterans may be present Venous thrombosis, varicosities and phlebitis are commonly found The heart is enlarged Coronary occlusions and cerebral vascular accidents are common

Enlargement of the liver is the rule Cirrhosis of the liver may be an accompaniment Splenomegaly is present in 9 of every 10 cases The spleen may vary greatly in size, and in rare instances it may even extend to the pelvis Sudden pain in the splenic region followed by a friction rub is indicative of infarction

The mucous membranes of the eyes appear congested, cyanotic, or even bloodshot. On examination of the eyegrounds the vessels are observed to be engorged, tortuous and irregular in diameter, the veins are dark and the retina is deeply colored Papilledema and embolism of the central retinal artery may occasionally be found.

On examination of the blood, erythrocyte counts of 6,000,000 to 10,000,000, or 12,000,000 per cubic millimeter are common In instances of marked polycythemia the mean corpuscular volume is reduced below normal Hemoglobin values of 17 to 24 gm per 100 ml accompany the polycythemia However, the hemoglobin may [illegible] mean corp[illegible] may be re[illegible] with polyc[illegible],000 or 40,000 or higher, the increase is in the myeloid leukocytes and the metamyelocytes. The blood platelets are increased to 1,000,000 to 2,000,000 per cubic millimeter The clot retracts poorly The viscosity of the blood may be *5 to 8 times* greater than normal The specific gravity is 1 075 to 1 080, as compared with 1 052 to 1 063 normally. The viscosity and specific gravity of the serum are less than is normal The sedimentation rate of polycythemic blood is delayed. The hematocrit percentage is markedly elevated The reading is found to be 60 or higher

in many of these patients. This increase in the hematocrit is in accord with high specific gravity and greater viscosity of the blood. The total blood volume is increased It may be as great at 121 to 246 ml. per kilogram of body weight, as compared with the normal mean volume of 87 ml. The plasma volume is not increased

The basal metabolic rate may be increased in some

The findings on analysis of the urine are not significant

DIAGNOSIS. The presence of cyanosis, splenomegaly, polycythemia, polychromatophilia, leukocytosis, and thrombocytosis usually suffices for a diagnosis of polycythemia vera. An increased total blood volume and an increased hematocrit are important diagnostic assurances Polycythemia vera is differentiated from a secondary polycythemia by the absence of chronic cardiac or pulmonary disease in those living at an altitude of less than one mile

The course may be chronic and 10 to 15 years or more in duration without serious complications In some the disease seems to remain stationary for years However, serious symptoms may develop at any time. The most serious development, which may cause sudden death, is occlusion of the coronary or cerebral arteries.

Relative and Transient Polycythemias. The causes for a *transient polycythemia* are more numerous and varied than those of *relative polycythemia* but usually find their origin in disease of the heart or lungs The commonest cause of a relative polycythemia is dehydration The total blood volume is reduced in relative polycythemia owing to the decrease in plasma volume, whereas in *absolute polycythemia* the total blood volume is normal or increased. Transient polycythemia occurs when there is a mixing and shunting of even small amounts of blood from the pulmonary circuit. The common defects producing such shunting of blood are pulmonary stenosis, usually with defective ventricular or auricular septum, patent foramen ovale or patent ductus arteriosus; persistent truncus arteriosus; complete transposition of arterial trunks; and the tetralogy of Fallot. These patients are markedly cyanotic. They have clubbing of the fingers and toes, and sometimes stunted growth since the heart lesions are of congenital origin

Polycythemia of mild degree occurs in some acquired heart disease such as mitral stenosis when there is anoxemia as the result of decreased cardiac reserve with an impaired systemic circulation and changes in the pulmonary tissues

Emphysema is the common chronic pulmonary condition which produces cyanosis and in time polycythemia. Silicosis, cavernous pulmonary hemangioma and pulmonary arteriovenous fistula are associated with polycythemia, cyanosis, hemoptysis and clubbing of the fingers

Exposure to high altitudes may be accompanied by acute symptoms of fatigue, dizziness, headache, nausea, ringing in the ears, and occasionally vomiting, chills, and prostration When adaptation occurs, the symptoms disappear with a regular appearance of polycythemia. Some individuals, however, even though they are acclimatized to high altitudes, may suffer from an insidious disorder known as *chronic mountain sickness* (Monge's disease) In chronic mountain sickness a state of tissue anoxemia may develop

Those affected by chronic altitude sickness are usually in the fourth to sixth decades of life Monge described (1) an emphysematous type and (2) an erythremic type.

In the *emphysematous type* there are chronic dyspnea, frequent bronchitis, laryngitis and cyanosis. There is a symptomatic improvement on residence at lower altitudes. In the *erythremic type* there are a reduction in mental and physical fitness, occipital headache, and an erythremic color of the face while at rest. On exertion the face is cyanotic. Epistaxis, nausea, vomiting, diminution of vision, and paresthesias may ensue if exertion is not stopped The disorder may progress, irrespective of exertion, to aphonia (aphonia of dyspnea), lethargy, and coma The

skin and scleras are deeply colored, the tongue is thickened, the hands are enlarged, and the fingers are clubbed

On examination it may be impossible to determine whether or not there is left-sided heart failure. Polycythemia is present, and it is more marked than in the other residents at the same altitude who do not have symptoms. Cell counts of 7,000,000 to 9,000,000 per cubic millimeter of blood are common There is a corresponding rise in hemoglobin and volume of packed red cells The blood volume is increased The van den Bergh reaction is indirect, and the concentration of bilirubin is increased.

Descent to sea level brings about complete relief of symptoms and thus establishes the diagnosis

Polycythemia may be associated with the presence of subtentorial tumors and Cushing's disease and Cushing's syndrome

Chronic poisoning by coal-tar derivatives, anilin and its derivatives, gum shellac, phosphorus, and metals, such as manganese, mercury, iron, bismuth subnitrate, arsenicals and cobalt, may produce polycythemia (see Chemical Agents, Chapter 19).

DISEASES OF THE ESOPHAGUS, ABDOMINAL WALL AND ABDOMINAL CONTENTS EXCLUSIVE OF THE ENDOCRINE GLANDS, SPLEEN AND GENITOURINARY TRACT

MANIFESTATIONS OF DIGESTIVE DISEASE

Anorexia. The term anorexia refers to the lack or loss of appetite for food. Anorexia is caused by organic disease, by functional disorders, and by many chronic wasting diseases attended by pain The commonest of all causes for anorexia is fever.

One type of primary anorexia, anorexia nervosa, has been described as a clinical entity Berkman summarized the sequence of events in anorexia nervosa as follows: Usually a primary psychic disturbance is obvious and seems to be directly responsible for the loss of appetite The reduction in the intake of food leads to inanition, which is associated with a lowering of the metabolic rate. The lowered metabolic rate means reduced food requirements Most of the weight is lost during the early part of the disease Sooner or later the weight becomes more stationary. This lowering in the rate of metabolism may be looked upon as a protective mechanism.

The clinical features of anorexia nervosa are a primary loss of appetite with an actual revulsion against food, often associated with vomiting after the taking of food, and marked loss in weight with surprisingly little loss in strength for a long period of time Amenorrhea is frequent

Physical examination often reveals a dry parched skin with bruise marks and eczema A brownish pigmentation may be present In many patients the extremities are cold and blue The temperature may be subnormal, the pulse slow and the systolic blood pressure low. The basal metabolic rate is almost universally −15 to −25 per cent

The ailment may prove to be extremely serious and in an occasional case may be fatal, as the result of exhaustion, pneumonia, or some other secondary infection. The diagnosis can be made only after the possibility of existing organic disease has been eliminated

Abdominal Pain. The mechanisms of abdominal pain are not well known However, abdominal pain can arise (1) in the viscera, when it is known as pain of visceral origin, (2) in the parietes or (3) in a viscus from which it is referred to a distant part (referred pain; see Chapter 2).

Visceral Pain. True visceral pain is produced by increased intravisceral pressure as the result of failure of relaxation or distention of the visceral musculature. This type [illegible] ossibly as a cramplike sensation [illegible] instances it may be relieved by [illegible] in intravisceral pressure, or by the development of gangrene

Pain provoked by obstruction to the bowel, spasm of the bile duct or ureter or blood vessels, the initial pain of acute appendicitis and of acute cholecystitis, and the pain which is present in some instances of ulcer with its associated pylorospasm, gastrospasm, or cardiospasm, are examples of true visceral pain

diseases of the nervous system, particularly neurasthenia, psychoneurosis, psychosis, brain tumor and cerebrospinal syphilis.

Parorexia. Parorexia denotes an appetite for unusual foods or a perversion of normal appetite. It is not concerned with the mechanism of hunger. In some instances, it may be a desire for spices, highly seasoned food or acid foods. Parorexia usually is associated with a psychoneurosis or a psychosis. In patients in the latter group actual depravities in appetite may develop. This is pica, a desire for ingesting things other than food In certain of the psychoses pica may change to allotriophagy, a desire for offensive food

Dysphagia. Dysphagia may be produced by anything which interferes with the normal act of deglutition in the mouth, the upper part of the respiratory passage, or the pharynx, or in the cervical portion of the esophagus, the midesophagus, or the lower 2 or 3 inches of the esophagus.

Lesions of the mouth or the tongue which are painful may cause dysphagia. In affections of the pharynx and larynx difficulty in deglutition occurs synchronously with the passage of the bolus from the mouth into the pharynx and upper part of the esophagus The pharyngeal and laryngeal affections which interfere with swallowing include acute or chronic infections, retropharyngeal abscess, and paralysis. The bulbar type of syringomyelia, strokes, and other bulbar lesions may cause weakness of the pharynx and loss of power to swallow. Myasthenia gravis may act in this way. If abnormal deglutition is associated with strangulation, coughing, or nasal regurgitation, central lesions of the bulbar type, myasthenia gravis, or diseases irritating the ninth or tenth cranial nerves are usually present A fistulous communication between the esophagus and the trachea or a bronchus may cause dysphagia, strangulation and coughing Malignant disease of the epiglottis or the arytenoid cartilages and pharyngeal pouches may cause dysphagia

Dysphagia occurring from 2 to 5 seconds after swallowing is caused by disorders of the proximal portion of the esophagus. Dysphagia occurs frequently as a symptom of lesions of the middle portion of the esophagus

Discomfort in the region of the ensiform cartilage, coming on from 5 to 15 seconds after swallowing, is suggestive of disease in the lower portion of the esophagus Diseases of the cardiac end of the stomach and hiatal hernia may cause dysphagia

Regurgitation and Rumination. *Regurgitation* is the ejection of chyme or gastric juice into the mouth It is distinguished from vomiting by the small quantities of material ejected and by lack of the participation of the action of the accessory muscles (diaphragm and thoracic muscles) which serve in vomiting

When food is regurgitated into the mouth, if it is chewed and swallowed again, these acts comprise the phenomenon of *rumination*. The term is also used to describe the act of regurgitating food back into the mouth and reswallowing it rather than expectorating it. The mechanism and clinical significance of rumination are similar to those of regurgitation except that the food has not been expelled, because it is not disagreeable to the taste and more often because the act of expelling it is not condoned by custom Rumination is an infrequent and an unimportant symptom However, it may occur in more than one member of a family

Sitophobia. The term sitophobia is used to describe a fear of eating because of painful sensations which have occurred after eating. Sitophobia is frequently a manifestation of anxiety, although it may be due to organic disease in the esophagus or the stomach causing distress after the ingestion of food

Belching, Aerophagia and Pneumatosis. A small gas bubble or "magenblase" is present in the normal stomach, and in the absence of any physiologic derangement the eructation or belching of gas may occur from the stomach once or twice after a large meal.

Air residing in the mouth and pharynx may remain in the lower part of the

esophagus The patient learns to bring it up voluntarily with a loud report. At times, without bringing the air up, the patient continues to reswallow, so that an increased amount of air accumulates in the stomach. After swallowed air enters the stomach, it is not always possible to eructate it voluntarily. Involuntary eructation of gas commonly is associated with the act of *aerophagia*

The neurotic person in whom aerophagia and belching develop likes to put on the act before an audience, hoping to impress his family or the physician with the seriousness of the complaint. The habit may be formed by patients who are not psychoneurotic In the latter it is easily corrected by an explanation of the harmful effect. These patients are instructed to open the mouth when there is a desire to eructate The treatment of the psychoneurotic aerophagic is disappointing.

The term *pneumatosis* often is used to describe attacks of gastric distension, dyspnea, or precordial oppression due to pressure by the stomach, inflated with excessive air, on the left leaflet of the diaphragm. The symptoms complained of are shortness of breath, a smothering sensation, cardiac pain, palpitation and sometimes a fear of impending death The syndrome attends aerophagia

Borborygmus. Borborygmus is defined as a gurgling of fluid and gas in the intestine due to peristaltic activity It may be the initial complaint in beginning obstruction of the intestinal tract from any cause In other cases, the gurgling sounds may depend on intestinal hypermotility attending emotional tension and aerophagia.

Borborygmus is a frequent complaint of asthenic, splanchnoptotic, underweight women At times the noises produced by peristaltic activity in these patients may be heard some distance away from them. Unless the symptom is of recent origin it is not often of serious importance to anyone except the psychoneurotic patient.

Expulsion of Flatus. An occasional expulsion of flatus is a normal phenomenon Beazel and Ivy measured the colonic flatus egested in 24 hours by 5 "normal" ambulatory students and found the mean average quantity to be 527 ml. These subjects were unaware of intestinal gas and they were not conscious of passing gas at the time of stool Evidently patients who consciously expel flatus must harbor large amounts of gas in the colon, for normally gas sufficient to give rise to the conscious expulsion of flatus, except during the act of defecation, does not reside in the distal portion of the colon

Flatus is associated with constipation. Often air is introduced by laxatives and enemas used in the treatment of constipation. Increased amounts of intestinal flatus attend poorly balanced diets, particularly the ingestion of excessive quantities of cellulose, beans or other legumes Food incompatibility or idiosyncrasy may give rise to excessive gas in the colon Flatus is present in diseases accompanied by defective intestinal absorption such as steatorrhea, sprue, regional enteritis, nutritional deficiency states, and occasionally after ingestion of excessive carbohydrates.

A Sense of Fullness. A feeling of fullness or gaseous distension is often complained of by those who have diverse digestive disturbances This sense of fullness may not be easily differentiated from a feeling of early satiety experienced after the eating of only a small amount of food Usually the latter symptom is of serious import, if the food intake becomes progressively decreased

Any abdominal lesion capable of producing pain may be associated with a vague sense of fullness or pressure rather than pain if the stimulus arising from the lesion is inadequate or if the pain threshold is high

A feeling of fullness or pressure situated in the epigastrium is most frequently of functional origin Air swallowing, the bolting of food, overeating and eating when fatigued or nervously overwrought are the commonest causes

Hematemesis and Melena. The term hematemesis refers to the vomiting of blood, whereas hemoptysis refers to the spitting of blood

The term melena refers to the passage of black tarry feces, usually resulting from hemorrhage into the upper part of the alimentary canal The causes for hem-

atemesis and for melena are often the same, and therefore in this discussion the two conditions will be considered together.

The quantity of blood required for the production of melena must vary Perhaps 2 fluid ounces (about 60 ml) of blood, free in the upper part of the intestinal tract, if passed quickly along the intestine, could cause a tarry stool. If there is not a quickened passage of blood through the small intestine, a larger amount of blood is required before a tarry stool is produced. *Not all black or tarry stools are due to the passage of blood* Melena may be simulated by alterations in the color of the feces following the ingestion of iron, charcoal, bismuth, neoprontosil, beets, blueberries, spinach, and other foods and drinks.

CAUSES. In order to enumerate, the following list is given which is the classification of melena by Balfour as modified by Bockus

A *Intragastric and Duodenal Causes* (1) Peptic ulcer (including duodenal and postoperative ulcers), (2) gastritis and duodenitis (erosions), (3) gastric malignant disease; (4) syphilis and tuberculosis of the stomach, (5) benign tumor of the stomach or duodenum; (6) postoperative hemorrhage; (7) rupture of a sclerotic blood vessel, (8) gastric crisis of tabes dorsalis; (9) supradiaphragmatic stomach (hiatus hernia) and (10) trauma

B. *Extragastric and Extraduodenal Causes* (1) Cirrhosis of the liver; (2) portal or mesenteric thrombosis (portal hypertension due to other causes); (3) splenic diseases. splenic anemia, Banti's syndrome (congestive splenomegaly, and other types of splenomegaly), (4) diseases of the esophagus: malignant or benign tumor, peptic ulcer, esophagitis and erosions, syphilis, tuberculosis and actinomycosis, diverticula and foreign body, (5) blood diseases purpura, polycythemia, hemophilia, pseudohemophilia or fibrinopenia, hereditary hemorrhagic angiomatosis, hemorrhagic disease of the newborn, pernicious anemia, hemolytic jaundice, Hodgkin's disease, and leukemia; (6) jaundice (prothrombin deficiency), (7) diseases of gallbladder, appendix and pancreas (carcinoma of pancreas involving the duodenum, gallstone or malignant lesion eroding into the stomach or duodenum), (8) lesions of the small intestine. benign and malignant tumors, carcinoma of the papilla of Vater, (9) cardiac and pulmonary disease, (10) other systemic causes (toxic, infectious and nutritional conditions and shock); (11) aneurysm or abscess ruptured into the gastrointestinal tract, (12) swallowed blood. epistaxis, hemoptysis, bleeding from mouth and pharynx, and malingering, (13) vicarious menstruation and (14) bleeding internal hemorrhoids, fissures and rectal polyps.

This is a long list of diseases and conditions which may cause intestinal bleeding, many of which will never be observed during a lifetime of the practice of medicine The commoner causes only will be considered here The uncommon causes are considered in association with primary diseases of which they are a part.

Intragastric and Duodenal Causes In the series of hematemesis and melena recorded by Rivers and Wilbur 9 of every 10 patients had *peptic ulcer* Three of every 10 patients who have hematemesis or melena are in the fifth decade of life and 7 of every 10 are men

Rivers and Wilbur observed that hemorrhage often occurs from small congested vessels surrounding the ulcerated region or from vessels in the buds of vascular granulation tissue in the base of a peptic ulcer If one of these buds breaks off, profuse *bleeding is postulated Neither the size of the* ulcer nor the size of the bleeding vessels may have anything to do with the magnitude of the hemorrhage.

Pain is not thought of as a symptom of melena, but if pain is present and if it persists after a severe hemorrhage from a peptic ulcer it often indicates a continuation of bleeding and a luck of ulcer healing There are *no criteria* which, when followed, will establish the exact cause and site of the bleeding The hemorrhage on occasion may be due to ulcerations or erosions of hypertrophic gastritis or to

[illegible] —ntoms

denitis in many of the elderly patients

Cancer of the stomach, gastric syphilis and tuberculosis, benign tumors of the stomach, gastric crisis of syphilis, supradiaphragmatic stomach (hiatus hernia), trauma and extragastric causes must be included among the less common causes of massive hemorrhage.

Extragastric and Extraduodenal Causes. The extragastric and extraduodenal sources of bleeding are variable and often require extensive investigations to distinguish them one from another In a few cases the source of bleeding is never determined

Massive hematemesis or melena is seldom due to intrinsic disease of the esophagus Carcinoma, the commonest organic disease of the esophagus, is rarely complicated by severe hematemesis Among the very rare esophageal causes of hematemesis may be included congenital nevi, acute and chronic esophagitis, foreign body, diverticulitis, syphilis, tuberculosis, and actinomycosis of the esophagus

The pathologic conditions of the small intestine which cause hemorrhage and melena are acute enteritis and chronic enteritis Regional involvement of the various segments of the small intestine, particularly the terminal portion of the ileum by regional enteritis is not a common cause of large hemorrhages, but slow bleeding occurs in this disease Benign ulcer of the ileum with or without ectopic tissue may cause hemorrhage Meckel's diverticulum containing ectopic tissue (often gastric) may cause massive hemorrhages Benign and malignant polyps or any sort of malignant lesions cause bleeding in some instances Diverticula of the small intestine are a rare cause of bleeding.

In the colon the common conditions causing melena are bacillary dysentery, idiopathic ulcerative colitis, amebic colitis (occasionally), polyps and carcinoma. Diverticulum of the colon rarely causes bleeding Rectal bleeding in a patient who has diverticulosis is not usually from a diverticulum but often from a polyp which has not been discovered

Melena is most commonly due to hemorrhoids. Usually in hemorrhoidal bleeding the blood is bright red and streaked on the stools or may drip from the anus during defecation In rare instances hemorrhoids may bleed suddenly while the patient is walking The causes of melena of rectal origin are considered with anorectal diseases

The bleeding in cirrhosis of the liver arises from varicose esophageal veins. The hemorrhage in splenic anemia may prove fatal immediately, or repeated bleeding may occur over a period of 10 or 15 years Other types of splenomegaly, not of congestive origin, rarely cause severe hemorrhage Balfour expressed the belief that the bleeding is not mechanical in origin, since hemorrhage is rare in myelogenous leukemia and in hemolytic icterus, conditions characterized by great splenic enlargement

Chronic ulcers and benign or malignant tumors of the mouth, tonsils and pharynx are causes of the swallowing of sufficient blood to produce hematemesis and melena Gingivitis due to scurvy or to the administration of mercury may cause large amounts of blood to be swallowed and subsequently vomited or passed on through the bowel

Massive hemorrhage may occur in any type of jaundice It is exceedingly rare in hemolytic icterus and in hypertrophic biliary cirrhosis and commoner in association with obstructive jaundice

Carcinoma of the papilla of Vater, and isolated primary tumors or ulcers in the small intestine, may be the source of melena. In congestive right-sided heart [illegible] ...ase and, occasionally, in ad- [illegible] ... occur.

[illegible] ...ed with massive bleeding are [illegible] ..., malaria, yellow fever and

Bleeding into the upper part of the gastrointestinal tract, particularly after trauma or operation, may be caused by hemophilia. Only males are hemophilic, but pseudohemophilia affects both sexes and may cause melena and hematemesis associated with cutaneous and mucosal hemorrhages, and greatly delayed bleeding and coagulation times from the lack of fibrinogen (afibrinogenemia). Conditions similar in manifestations to afibrinogenemia are: congenital hypofibrinogenemia and idiopathic hypothrombinemia (see Chapter 12).

Hematemesis, occurring in an adult showing telangiectasis of cutaneous and mucous membranes, particularly on the face, or in the nose, mouth or pharynx, should suggest the possibility of hereditary hemorrhagic angiomatosis somewhere in the digestive tube

Occasionally a fatal gastrointestinal hemorrhage occurs in polycythemia Thrombocytopenic purpura, either of the essential type (Werlhof's disease) or the symptomatic type, may be associated with a massive hemorrhage into the upper part of the gastrointestinal tract Petechiae or ecchymoses often occur in the skin without erythema, swelling or inflammation

In massive hemorrhages a history from the family, usually of a previous episode of hematemesis or melena, points toward the diagnostic probability of peptic ulcer

SYMPTOMS. There is a sudden desire to defecate which is accompanied by weakness, chilliness, pallor and often nausea Syncope may occur during or soon after the act of defecation Vomiting of blood may take place before or after the bowel movement These symptoms may awake the patient from sleep Stoic individuals may not be alarmed over the passage of a tarry or black stool or concerned about the vomiting of blood until they become so weakened that they cannot work. The sight of blood in the vomitus or in the bowel movement, and the weakness, will cause most patients to seek aid immediately.

EXAMINATION. During the time the hemorrhage is in progress the extent of the examinations must be left to the judgment of the examiner The general rule is that only essential examinations and procedures are conducted at this time The patient remains quiet.

If the hemorrhage is massive, there is shock Shock may come immediately after the loss of a large amount of blood or it may not be manifested for several hours

Hyperazotemia may follow a massive hemorrhage into the upper part of the intestinal tract in the absence of decreased renal functional activity, dehydration, starvation, or shock The hyperazotemia is an expression of the amount of blood protein digested and absorbed from the bowel Hyperazotemia of alimentary origin is often associated with fever and toxic symptoms which begin about 2 days after the onset of bleeding if a large amount of blood has remained in the bowel

Hyperazotemia present after gastrointestinal hemorrhage is more frequently due to dehydration resulting in oliguria and anuria When there is a suppression of urinary output there is a decrease in the excretion of urea followed by an increased concentration of urea in the blood Thus the blood urea nitrogen concentration is greater. A hyperazotemia may be due to a renal insufficiency and not be related to the melena In an occasional patient there may be hyperazotemia as the result of a combination of all of these factors, namely, (1) absorption of blood protein and (2) dehydration and absorption of blood protein, plus an impaired renal function.

A failure of the blood urea nitrogen concentration to return to normal may be due to (1) continuation of the renal impairment as a result of the shock and dehydration, (2) continued bleeding or exacerbation of the hemorrhage or (3) impaired renal function due to renal disease The blood urea nitrogen concentration together with the blood count, hematocrit reading, blood pressure and condition of

the circulation is helpful in establishing or disproving the existence of continued bleeding or renewed bleeding. The mortality rate from hemorrhage when the blood urea nitrogen concentration is more than 100 mg per 100 ml, a state which is associated with renal disease and permanent renal insufficiency, is very high

A complete blood count and hemoglobin reading, blood grouping and determination of the Rh factor and concentration of blood urea are performed routinely on patients who have massive hemorrhage. There should be a reduction in the erythrocyte count and hemoglobin concentration and varying degrees of leukocytosis (12,000 or more per cubic millimeter). On rare occasions there is a pronounced leukocytosis

THE ESOPHAGUS

The esophagus is the only organ of the digestive system that is situated within the thorax In its passage through the thoracic cage it may be seriously affected by diseases of the respiratory and vascular organs More particularly, the esophagus is affected by diseases in the mediastinum It therefore has been mentioned from *time to time in the diagnosis of respiratory, cardiovascular and mediastinal* conditions

In looking into the throat through the mouth, the posterior wall of the pharynx is seen at the level of the body of the second cervical vertebra Seven structures open into the pharynx, namely, the two posterior nares, the two eustachian tubes, the mouth, the larynx, and the esophagus The esophagus begins at the lower end and is the posterior outlet of the pharynx.

PAIN The upper portion of the esophagus is supplied by the recurrent laryngeal nerves and the right and left vagus nerves It is the consensus that pain in cardiospasm is conveyed by vagal afferent fibers In the medulla vagus fibers and the sensory nucleus are in close apposition to the descending tract of the trigeminal nerve, which constitutes a possible route for pain referred to the face in esophageal disorders The somatic sensory nerve from the nodose ganglion of the vagus innervates the external auditory canal and constitutes the most logical pathway for the reference of pain to the ear which occasionally is present in diseases of the esophagus

Esophageal pain is dependent on the state of tension of the esophagus The more severe the pain becomes, the wider is its distribution Pain due to disturbances in the upper portion of the esophagus is likely to be situated over the point corresponding to the underlying esophageal lesion Disturbances in the lower portion of the esophagus give rise to a much more diversified distribution

EXAMINATION Palpation of the esophagus is possible only in the neck, usually on the left side, behind the trachea A distinct tumor found here may be a diverticulum distended with food or fluid, or an abscess from caries of the cervical vertebrae

Auscultation of the esophagus is occasionally of some diagnostic value The stethoscope is placed posteriorly just to the left of the spinal column, about the level of the sixth thoracic vertebra, while the patient swallows a mouthful of water. At the instant of swallowing, a sound (deglutitory) is heard, followed in 6 or 7 seconds by an esophageal bruit, a sound like that heard in one's own ears when swallowing saliva Three to 5 seconds later ensues a secondary sound caused either by the fluid entering the stomach or by regurgitation of air bubbles Delayed appearance of the last-mentioned sounds may be present in esophageal obstruction.

Deformities. Deformities of the esophagus arise from diseases due to prenatal influences and acquired disease of postnatal life In any one patient affected by an esophageal deformity it may be impossible to assign proper values to one or the other of these etiologic categories For instance, a considerable degree of stricturing of the esophagus due to prenatal influence may be present and compatible with health If, however, an acquired disease such as esophagitis resulting from an infec-

Bleeding into the upper part of the gastrointestinal
trauma or operation, may be caused by hemophilia. O
but pseudohemophilia affects both sexes and may caus
associated with cutaneous and mucosal hemorrhages, a
and coagulation times from the lack of fibrinogen (a

THE ESOPHAGUS

The esophagus is the only organ of the digestive system that is situated within the thorax In its passage through the thoracic cage it may be seriously affected by diseases of the respiratory and vascular organs More particularly, the esophagus is affected by diseases in the mediastinum It therefore has been mentioned from time to time in the diagnosis of respiratory, cardiovascular and mediastinal conditions.

In looking into the throat through the mouth, the posterior wall of the pharynx is seen at the level of the body of the second cervical vertebra Seven structures open into the pharynx, namely, the two posterior nares, the two eustachian tubes, the mouth, the larynx, and the esophagus The esophagus begins at the lower end and is the posterior outlet of the pharynx

PAIN. The upper portion of the esophagus is supplied by the recurrent laryngeal nerves and the right and left vagus nerves It is the consensus that pain in cardiospasm is conveyed by vagal afferent fibers In the medulla vagus fibers and the sensory nucleus are in close apposition to the descending tract of the trigeminal nerve, which constitutes a possible route for pain referred to the face in esophageal disorders The somatic sensory nerve from the nodose ganglion of the vagus innervates the external auditory canal and constitutes the most logical pathway for the reference of pain to the ear which occasionally is present in diseases of the esophagus

Esophageal pain is dependent on the state of tension of the esophagus The more severe the pain becomes, the wider is its distribution Pain due to disturbances in the upper portion of the esophagus is likely to be situated over the point corresponding to the underlying esophageal lesion Disturbances in the lower portion of the esophagus give rise to a much more diversified distribution

EXAMINATION. Palpation of the esophagus is possible only in the neck, usually on the left side, behind the trachea A distinct tumor found here may be a diverticulum distended with food or fluid, or an abscess from caries of the cervical vertebrae.

Auscultation of the esophagus is occasionally of some diagnostic value The stethoscope is placed posteriorly just to the left of the spinal column, about the level of the sixth thoracic vertebra, while the patient swallows a mouthful of water. At the instant of swallowing, a sound (deglutitory) is heard, followed in 6 or 7 seconds by an esophageal bruit, a sound like that heard in one's own ears when swallowing saliva Three to 5 seconds later ensues a secondary sound caused either by the fluid entering the stomach or by regurgitation of air bubbles Delayed appearance of the last-mentioned sounds may be present in esophageal obstruction.

Deformities. Deformities of the esophagus arise from diseases due to prenatal influences and acquired disease of postnatal life In any one patient affected by an esophageal deformity it may be impossible to assign proper values to one or the other of these etiologic categories For instance, a considerable degree of stricturing of the esophagus due to prenatal influence may be present and compatible with health If, however, an acquired disease such as esophagitis resulting from an infec-

tion, a poison, or lodging of a foreign body arises and adds further stricturing, though of a minor degree, invalidism may follow.

Deformities Due to Prenatal Influences. The esophagus may be absent or atretic, that is, represented by a fibrous cord. The atretic process may be segmental. In early embryonic life the esophagus is normally occluded by a process known as epithelial occlusion Thus the atresias of the esophagus are persistent if this normal process of development stops

In an occasional individual the esophagus may be doubled. Doubling may involve a part or the entire esophagus.

There may be a completely developed esophagus which is too long (dolichoesophagus) or too short Minor degrees of enlargement are dilatations The esophagus may be very large in diameter (giant esophagus).

In association with diaphragmatic and other anomalies of the digestive tube, or anomalies elsewhere in the body, the esophagus may participate in various malformations Congenital webs or bands may constitute causes of narrowing of the esophagus Valvular folds in the esophagus at the level of the diaphragmatic hiatus have been described Such anomalies are probably produced by abnormalities of the crura of the diaphragm

Throughout these descriptions it is remembered that in many of the diseases of the esophagus unknown deformities due to prenatal influence may be present and may be adding their bit to the severity of the disease under consideration.

Atresia. Congenital atresia of the esophagus occurs rarely, and then often in association with some other anomaly of the gastrointestinal tract incompatible with life. However, on occasion, there will be seen a young patient who has a partial or a segmental atresia These lesions often are symptomless unless the esophagus is injured by swallowing a caustic substance

Stenosis. Stenosis of the esophagus may be (1) congenital or (2) acquired

Congenital Stenosis. Congenital stenosis may be due to a fibrous narrowing at any level in the esophagus This malformation in infants is much less frequently encountered than is atresia In adulthood mild stenosis of congenital origin may predispose to the lodging of solid objects or the formation of strictures after esophagitis

Ordinarily a history of dysphagia or regurgitation dates from birth, but may be of little consequence until solid food is added to the diet The degree of dilatation of the esophagus above the stricture will depend on the level of the point of narrowing If it is high up, the dilatation may be very slight In the majority of cases the partial obstruction is high up in the esophagus, usually at the cricoid level Roentgenographic examination is diagnostic.

Acquired Stenosis (Esophageal Stricture). An acquired stenosis usually results from the accidental or intentional swallowing of caustic substances such as lye, acids, bichloride of mercury or ammonia These strictures occur most frequently at the crossing of the left bronchus over the esophagus, in the region of the cricopharyngeus muscle, and at the hiatus Acquired stenosis from infections; from peptic ulcer of the lower part of the esophagus, from trauma to the esophagus by swallowed foreign bodies, and from the vomiting of pregnancy is rare. More commonly no etiologic factor can be found

Many patients who have obstruction of the lower part of the esophagus give a history of a slow insidious onset of dysphagia In the presence of negative results of biopsy a definite diagnosis cannot be established until sufficient time has elapsed after dilatation of a stricture to prove with a fair degree of certainty that the stricture is idiopathic and benign and not of malignant nature A slight congenital stenosis may have been present and unnoticed or ignored until obstruction occurred as a [illegible] in the stenotic region of a bolus of food [illegible] lowed, in some patients [illegible] the swallowing function returns to normal for a while. Dysphagia then returns and becomes progressively worse A severe esophageal injury from swallowing of a caustic substance will not be followed by a symptom-free period The rapidity with which dysphagia develops

depends on the extent and the severity of the injury. As the result of acute starvation in advanced obstructions there are rapid loss of body weight and anemia.

Diagnosis. Roentgenologic examination of the esophagus is the first examination routinely performed and is the most important diagnostically. Esophagoscopic examination permits of visualization of stricture and is essential for the establishment of a definite diagnosis and for securing tissue for microscopic study.

The differential diagnosis between benign stricture, cardiospasm and malignant disease can be made only by biopsy Strictures following the swallowing of lye are frequently multiple.

Diverticula. Diverticula of the esophagus occur in elderly men and women. They are designated, in accordance with their anatomic position, as (1) the pharyngo-esophageal, (2) the epibronchial and (3) the epiphrenal or supradiaphragmatic diverticula The hypopharyngeal pouch is rare and when present does not produce digestive symptoms The pharyngo-esophageal diverticulum is described on page 166

Epibronchial Diverticulum (*Traction Diverticulum*) Epibronchial diverticula occur opposite the bifurcation of the trachea or near the left main bronchus, as the result, usually, of tuberculosis of lymph nodes which are adherent to the esophagus. Disease of the vertebrae may give rise to one of these diverticula of traction type. These diverticula rarely exceed 2 cm in diameter, and may fill and empty readily because of wide mouths, absence of necks, and upward pointing of the sac

Traction diverticula seldom cause symptoms Occasionally they perforate and thus cause mediastinal abscess or esophagobronchial fistula If partial obstruction to the esophagus occurs, a pulsion element may cause further development of the pouch and provoke symptoms

Diagnosis is made by roentgenologic examination

Epiphrenal Diverticulum. An epiphrenal diverticulum is situated in the esophagus near the diaphragmatic hiatus It is a true diverticulum of rare occurrence

The cause of this diverticulum is not known Once started, it usually enlarges in a distalward direction toward the right

The symptoms are vague because of coexistent achalasia There are substernal pain, dysphagia, and vomiting of decomposed but not partly digested food. Regurgitation interferes with sleep

The diagnosis is confirmed by roentgenologic examination

Infections of the Esophagus. Esophagitis occurs in both acute and chronic forms The acute types follow acute infectious diseases, the swallowing of a highly caustic or irritating substance, trauma, excessive vomiting or esophageal intubation, as in treatment of intestinal obstruction and after abdominal operation

Acute Esophagitis. A frequent cause nowadays is trauma of intubation, of vomiting or of the two combined One half of those who have acute esophagitis have been subjected to an inlying nasal catheter and this has been associated with vomiting However, the ingestion of corrosive poisons, hot fluids, or foreign bodies, and such infections as pneumonia, diphtheria, smallpox, glanders, actinomycosis, and blastomycosis are causes of acute esophagitis Subsequent to diphtheria there may be paralysis of the esophagus without pain

The frequency of the association of peptic ulcer and acute esophagitis is reputed to be of common occurrence The acute esophagitis present at postmortem examination is believed to be the result of an agonal episode.

The symptoms of acute esophagitis may suggest a gastric disturbance Substernal pain with extension to the throat during and immediately after deglutition, dysphagia, and occasional hematemesis are characteristic.

Diagnosis in the early stages cannot be proved by roentgenologic examination, as a rule, but endoscopic examination can be used with caution and is the only definite means of diagnosis.

Chronic Esophagitis. Chronic esophagitis may be divided into primary esophagitis and esophagitis secondary either to some other esophageal disease or to disease of an adjacent organ.

Primary Chronic Esophagitis. The predisposing cause of primary chronic esophagitis is the ingestion of irritants such as pepper, hot or cold liquids, drugs and, most of all, alcohol

Secondary Chronic Esophagitis. An esophagitis secondary to obstructing lesions in the esophagus such as cancer, ulcer, cardiospasm, benign stenosis and possibly diverticulum is of a chronic type. It is due to stasis of secretions and food proximal to the point of obstruction Diseases of the thorax and mediastinum may cause esophagitis by contiguity, by interference with the blood supply of the esophagus, or by lymphatic spread of infection Chronic tracheobronchitis, mediastinitis and pressure from mediastinal tumors are accompanied by changes in the esophagus and symptoms subsequent thereto (see Mediastinal Tumors, page 577)

Esophagitis may be incident to a chronic passive congestion, as in congestive heart failure, chronic passive congestion of the lungs or the liver or spasm accompanied by gastric antiperistalsis, for instance, peptic esophagitis. Deficiency states may be accompanied by chronic esophagitis.

A diagnosis of a primary or a secondary chronic esophagitis can be established only by an endoscopic examination.

Tuberculosis of the Esophagus. Esophageal tuberculosis develops by an extension of tuberculous ulcerative pharyngitis, by a perforation into the esophagus of a tuberculous bronchial lymph node or by contiguity secondary to vertebral tuberculosis, and owing to a widespread miliary tuberculosis. Tuberculosis of the esophagus occurs from contact, as from the swallowing of infected tuberculous sputum or food, but rarely causes symptoms

Lesions of esophageal tuberculosis may be ulcerative or hyperplastic. The midportion near the bifurcation of the trachea is the site of predilection of tuberculous lesions, though they may occur in any part of the tube

A complaint of persistent dysphagia by a patient who has pulmonary tuberculosis suggests the possibility of tuberculosis of the esophagus However, tuberculosis of the hypopharynx or larynx is commoner and usually will be found to account for the esophageal symptoms

In the absence of other nontuberculous lesions such as cardiospasm, diverticulum, or cancer, and in the presence of a defect in the esophageal shadow in a roentgenogram suggestive of ulceration or narrowing of the esophagus, the diagnosis is usually certain The endoscopic appearance of the lesion may arouse the suspicion that tuberculosis is present, but a positive diagnosis cannot be made without biopsy of tissue and guinea pig inoculation

The primary tuberculous disease is usually far advanced when the symptoms of esophagitis occur, and the prognosis therefore is grave.

Syphilis of the Esophagus. Tertiary syphilis of the esophagus may be responsible for a chronic esophagitis A syphilitic ulcer of the esophagus may result from the occlusion to a sizable nutrient vessel caused by syphilitic periarteritis A widespread syphilitic submucosal fibrosis of the esophagus gives rise to extensive narrowing of the lumen When present, gummas are often situated in the lower part of the esophagus or may be situated in the diaphragm at the hiatus oesophageus and may produce obstruction.

Syphilitic esophageal lesions may cause fibrotic stenosis and subsequently spontaneous rupture of the esophagus.

An esophageal lesion occurring in a patient who has untreated syphilis is regarded as possibly syphilitic and so treated if carcinoma can be excluded by endoscopic methods of examination and biopsy studies

Fungous Infections of the Esophagus. A
cause esophagobronchial fistula The diagnosis c
agus depends on microscopic examination of ma
agoscope and positive cultures of this material
pathogenic potentials to cause disease.

Fungous lesions of the esophagus are rare eve
blastomycosis

Esophageal Fistulas. Carcinoma, peptic ul
and actinomycosis, as well as foreign body and
esophagus In the middle-aged patient the mos
fistula is an ulcerating carcinoma. Fistula from
municates with the trachea or a large bronchus
sages rarely perforate into the esophagus

Respiratory symptoms, such as cough ass
blood, mucus and food, dyspnea superimposed o
and dysphagia are characteristic In addition
primary disease In a patient who gives an ante
currence of strangulation after swallowing sugge

Often the fistula can be discovered by roent
aperture is not seen by the endoscopist

If the fistula is large and the strangulation
or peroral gastric intubation will be required (
may be tried Some patients who have bronch
years

Esophageal Diseases Due to Trauma or P
of the esophagus sustained in accidents and p
discovered at necropsy

The presence of a foreign body in the esoph
tures can be diagnosed

Foreign Bodies. The stoppage of a foreign

Therefore, after the removal of a food bolus o
agus, roentgenologic and often endoscopic exa

Foreign bodies such as fish bones may pu
pain and dysphagia Occasionally such an obje
mation of serious prognostic import

The diagnosis is evident from the history
vided the latter is performed by skilled hands

Rupture. The commonest cause of rupture
An esophageal rupture from instrumentation i
esophagus such as an esophagitis due to infecti

Rupture of the esophagus is followed by
choking sensation, retching, collapse, and ofte
ruptured from any other cause, the diagnosis is
examination

Esophageal Varices. The average age of the patient who has esophageal varices corresponds to the age incidence of portal cirrhosis (50 years), except in Banti's syndrome, which occurs at an earlier age.

When there is portal hypertension, an effort is made to establish collateral circulation, and the esophageal veins, because of the connection with the coronary vein and vasa brevia of the cardia, dilate and protrude into the lumen of the esophagus

Esophageal varices are symptomless When symptoms occur, they are referable to a single hemorrhage or to repeated hemorrhages as the result of rupture of a vein. There are often the accompanying symptoms of cirrhosis of the liver. The hemorrhage may be profuse and attended by death

Diagnosis of esophageal varices is made by roentgenoscopic examination The diagnosis may be suspected when hemorrhage occurs in a patient who has cirrhosis of the liver There may be value in performing both endoscopic and roentgenoscopic examination in order to determine the extent of the lesion

Hemangioma of the Esophagus. In a person who has dermal evidence or other manifestations of hemangiomas, there may be mild or profuse esophageal bleeding from one of these tumors These patients may be younger than those who bleed from esophageal varices or from portal hypertension, or they may be of the same age group as those who have Banti's disease Diagnosis is established by endoscopic examination

Deficiency Diseases of the Esophagus. *Plummer-Vinson Syndrome.* There is much to indicate that this syndrome is a type of iron deficiency anemia associated with a vitamin B complex deficiency Despite the plausibility of the theory of vitamin deficiency state, it has not been disproved that this syndrome is initially a hypochromic, microcytic anemia, an iron deficiency. The dysphagia in either case is best explained as the result of a pharyngo-esophagitis The psychic manifestations are concomitant or secondary, not primary.

A woman at the time of menopause who has a history of menstrual irregularity and a complaint of dysphagia accompanied by pallor, glossitis, pharyngitis, cutaneous changes, and enlarged spleen has a Plummer-Vinson syndrome, a vitamin B deficiency disease

The diagnosis of Plummer-Vinson syndrome is based on dysphagia, a microcytic hypochromic anemia and roentgenologic study which does not reveal an organic disease in the esophagus. Usually achlorhydria is present

Diseases of the Esophagus Due to Disturbances of Innervation. In most instances paralysis of the esophagus is situated in the pharynx and the upper part of the esophagus The paralysis may occur as a result of lesions of the vagus nerve, toxic neuritis or diphtheria A bulbar type of paralysis of the esophagus may be a complication of syringomyelia or the result of an atherosclerosis or any other bulbar lesions which give rise to dysphagia

Cardiospasm. Cardiospasm is known also as simple ectasia, atony and idiopathic dilatation of the esophagus, mega-esophagus, hiatal esophagism, functional hiatal stenosis, phrenospasm, preventriculosis and achalasia of the cardia

CAUSES. The following theories of cardiospasm have had their protagonists. (1) failure of relaxation of the cardia, (2) nutritional deficiency states, (3) psychogenic factors and (4) autonomic and other factors (Bockus)

1. Failure of Relaxation of the Cardia. In cardiospasm there may be failure of the [illegible] wave of contraction which is carrying [illegible] ophagus is not strong enough to over[illegible] ncter There are no objective data to support this contention.

2. Nutritional Deficiency States. Nutritional deficiency states have been held indirectly responsible in the etiology of some cases of cardiospasm There are only subjective data to support this contention.

3. Psychogenic Factors Often the onset of dysphagia follows nervous shock or grief, or emotional disturbances

4 Autonomic and Other Factors. A common cause of dysphagia is the too rapid swallowing of food or drink.

Peptic ulcer of the esophagus, esophagitis, and diverticulum in the lower part of the esophagus are in some instances responsible for the development of cardiospasm Toxic conditions caused by lead, alcohol, or the excessive use of tobacco may be accountable for the neuromuscular disturbances in some patients

SYMPTOMS. The symptoms commence with pain or discomfort, a sensation of pressure or burning or of food sticking temporarily at or near the lower end of the sternum In the beginning the symptoms may occur infrequently. Later the dysphagia recurs with increasing frequency and severity until eventually a sensation of fullness or discomfort behind the sternum may be almost continuous. The discomforts may be referred to the neck, lower jaw or region of the ears.

Pain resembling that of angina pectoris in distribution may be initiated by esophageal spasm The pain of cardiospasm is not provoked by exertion

Dysphagia may attend the ingestion of food or drink, an emotional upset, an acute infection or may appear during the night when the patient is recumbent, thus permitting some of the retained esophageal contents to pass into the trachea and respiratory passages, causing violent cough and choking.

Anemia, nutritional deficiencies and loss of body weight are commonly observed in those who have great and prolonged esophageal dilatation

A smooth constriction about an inch above the cardia, with or without dilatation of the esophagus, revealed on the roentgenogram justifies a provisional diagnosis of cardiospasm A history of dysphagia of years' duration indicates a benign stenosis. In some a period of observation, with several endoscopic and roentgenologic examinations, is required before a certain diagnosis of a benign lesion can be established.

A recurrence of symptoms may be anticipated following dilatation An occasional patient who has a cardiospasm will succumb to the effects of the disorder or of an accident during stretching of the esophagus

Diseases of the Esophagus Due to Unknown or Uncertain Cause. Single ulcers of the esophagus occur which are not peptic ulcers. These ulcers include lesions caused by the ingestion of caustics, by trauma, acute infectious diseases, traction diverticula, varicosities and those of indeterminate origin

Peptic Ulcer of the Esophagus. Esophageal peptic ulcers occur in the distal 3 inches (7.6 cm.) of the esophagus, frequently within 1½ inches (about 3 8 cm) of the cardia, and occasionally with extension into the cardiac end of the stomach. Often there is an accompanying peptic ulcer of either the stomach or the duodenum or of both.

Peptic ulcers may occur when there is a short esophagus or a diaphragmatic hernia They may result from regurgitation of acid gastric juice through a poorly functioning cardia, thus causing erosion and ulceration. Extensive surface burns may cause transient esophageal ulcers comparable to Curling's ulcer of the duodenum.

Peptic ulcer of the esophagus is often asymptomatic. When symptoms are present, they consist of pain and often dysphagia The pain, situated under the lower part of the sternum and often referred first to the back and then to the anterior part of the thoracic region, is the significant symptom It follows immediately after deglutition Pain which appears later after meals is due to an associated duodenal or gastric ulcer. Dysphagia may precede the occurrence of pain, may occur alone, or may be associated with regurgitation of food or drink

There may be anemia and loss of body weight and strength as the result of chronic bleeding Perforation may occur, which is usually fatal

Peptic ulcer of the esophagus is diagnosed by means of roentgenologic and endoscopic examinations

Tumors of the Esophagus. *Benign Tumors.* Benign tumors in the esophagus are rare. Perhaps these tumors occur at an earlier age than carcinomas. The sexes are equally affected

The commonest varieties of benign tumor are polyps, lipomas, myomas and fibromas. Other benign tumors less frequently encountered are papillomas, angiomas, hematomas, lymphangiomas and aberrant thyroid cysts The polyp is the commonest benign tumor in the esophagus.

Cysts occurring in the esophagus may be parasitic, dermoid, congenital, or retention cysts of the esophageal glands. At or near the bifurcation of the trachea is a common location for cysts These cysts may be the result of an imperfect separation of the embryologic connection between the esophagus and trachea.

Benign tumors cause symptoms like carcinoma of the esophagus except in patients younger than the patient who has esophageal carcinoma. Bleeding and dysphagia frequently occur from a benign tumor. Harrington reported an instance in which a long pedunculated polyp was ejected into the pharynx during the act of vomiting

The roentgenologic and the endoscopic examinations are essential for diagnosis The benign character of the tumor can never be established with certainty without histologic study

Malignant Tumors. Carcinoma of the esophagus generally occurs in the lower third of the viscus It is predominantly a disease of middle aged and aging men.

The two common histologic types of esophageal cancer are the squamous cell epithelioma and the adenocarcinoma The growth may project as a polypoid neoplasm into the esophagus or may encircle the esophagus and constrict its lumen In either case obstruction is a constant manifestation In some the tumor ulcerates and causes anemia, bleeding and early metastasis, and in these obstruction is late or absent

Carcinoma of the distal part of the esophagus often metastasizes to the liver, the cardiac end of the stomach, the inferior mediastinum, the lungs and occasionally to the vertebrae Carcinoma of the upper thoracic segment of the esophagus may spread to the trachea, and carcinoma of the upper third may invade the larynx, the pharynx, the thyroid or the recurrent laryngeal nerve

The symptoms commence with a sensation of food sticking and stopping on its way down The sensation is attended by substernal or neck pain After this symptom is established, there ensues a definite dysphagia The progress of the dysphagia is evident by the gradual elimination of solid food from the diet. In a few the first symptom appears after a foreign body has lodged in a narrowed, constricted esophagus and has been dislodged. More commonly the patient has had what is described as an inability to get the food down Then regurgitation or vomiting ensues Hoarseness is an uncommon complaint It is due to paralysis of the recurrent laryngeal nerve or is the result of direct extension of carcinoma into the larynx

A fistulous communication between the esophagus and the respiratory passages should be suspected from the onset of dyspnea and cough with the expectoration of blood, mucus and food Pulmonary abscesses, empyema and paralysis of a vocal cord rapidly ensue

The physical examination rarely reveals more than evidence of loss of weight and pallor The degree of emaciation may be extreme Occasionally lymph nodes may be palpated in the left supraclavicular, cervical, or axillary regions. The liver may be enlarged Frequently the swallowing sound on auscultation is delayed or absent

The diagnosis of carcinoma of the esophagus is based on endoscopic and roentgenoscopic examinations plus histologic examination of tissue removed for biopsy Negative results of biopsy, however, do not exclude absolutely the diagnosis of a malignant lesion It may be necessary to perform biopsy two or more times in a case of suspected carcinoma before malignant tissue is found Compression of the esophagus from an extrinsic lesion may cause great difficulty in diagnosis.

The average duration of life after the diagnosis has been established is approximately six months.

Sarcoma About 1 in 150 malignant lesions of the esophagus will prove to be a sarcoma. The symptoms are the same as those of carcinoma of the esophagus The findings on roentgenologic and esophagoscopic examinations do not distinguish sarcoma from carcinoma The differential diagnosis is made by a histologic study of tissue removed through the esophagoscope.

THE ABDOMEN

(Exclusive of the Pancreas, Spleen and Genitourinary Tract)

The abdomen comprises the section of the body that is anterior, in the center, to the lower portion of the thoracic, lumbar, sacral and coccygeal regions of the spinal column, and on the sides to the erector spinae and quadratus lumborum muscles. In front it extends from the diaphragm above to the rim of the pelvis below.

The shape of the abdomen is influenced by its bony support, by the tone of its muscles and the strength of its fascia, and by the size of the organs and the amount

ensiform

vertebra

ium—the

sixth and seventh costal cartilages meet at this point—also can be felt The seventh, eighth, ninth and tenth costal cartilages can be followed down to the lower border of the thorax The eleventh rib, which is free, can be distinguished The twelfth rib is often not palpable

The spines of the pubes as well as the upper edge of the pubic bones can be identified The depressions for the fasciae of the linea alba, lineae semilunares and lineae transversae are all more definite above the umbilicus than below it

REGIONS The abdomen arbitrarily is divided into regions so that the location of particular portions can be specified In precise descriptions the surface views are divided into 9 regions by 2 transverse and 2 longitudinal lines (Fig 13-1) The upper transverse line passes from the tip of the tenth rib, which corresponds to the lower end of the thorax, on one side to that of the other The lower transverse line passes from the anterior superior spine of the ilium on one side to that of the opposite, it is on a level with the second sacral vertebra. The two longitudinal lines pass directly up on each side from the middle of Poupart's ligament

The middle regions are the epigastric, the umbilical, and the hypogastric or pubic The lateral regions are the right and left hypochondriac, the right and left lumbar, and the right and left iliac

It is more convenient for descriptive purposes to divide the abdomen into four quadrants by a longitudinal median line and a transverse line through the umbilicus (Fig 13-2) Both of these divisions of the abdomen into regions are used and their usage depends on the applicability

LINES OR LINEAE There are certain lines on the abdomen, called linea alba, lineae semilunares, and lineae transversae, and sometimes there are present lineae albicantes

The *linea alba* passes in the median line from the ensiform cartilage to the symphysis pubis. It is formed by the fusion of the sheaths of the recti muscles A failure of fusion of these sheaths or a separation of them during the course of pregnancy or of the growth of large abdominal tumors may permit sufficient separation so that impulses originating in the abdomen can be felt

Between the transverse fibers of the sheaths of the recti muscles there may be gaps These gaps may be large enough to allow the subperitoneal fat to protrude and form a hernia in the median line which can be felt under the skin as a small, firm, rounded body

The *lineae semilunares* are not readily recognized by palpation.

On contraction of the rectus muscle in thin muscular persons grooves are seen on

Tumors of the Esophagus. ***Benign Tumors.*** Benign tumors in the esophagus are rare. Perhaps these tumors occur at an earlier age than carcinomas The sexes are equally affected

The commonest varieties of benign tumor are polyps, lipomas, myomas and fibromas Other benign tumors less frequently encountered are papillomas, angiomas, hematomas, lymphangiomas and aberrant thyroid cysts The polyp is the commonest benign tumor in the esophagus.

Cysts occurring in the esophagus may be parasitic, dermoid, congenital, or retention cysts of the esophageal glands. At or near the bifurcation of the trachea is a common location for cysts These cysts may be the result of an imperfect separation of the embryologic connection between the esophagus and trachea.

Benign tumors cause symptoms like carcinoma of the esophagus except in patients younger than the patient who has esophageal carcinoma Bleeding and dysphagia frequently occur from a benign tumor. Harrington reported an instance in which a long pedunculated polyp was ejected into the pharynx during the act of vomiting.

The roentgenologic and the endoscopic examinations are essential for diagnosis The benign character of the tumor can never be established with certainty without histologic study

Malignant Tumors. Carcinoma of the esophagus generally occurs in the lower third of the viscus It is predominantly a disease of middle aged and aging men.

The two common histologic types of esophageal cancer are the squamous cell epithelioma and the adenocarcinoma. The growth may project as a polypoid neoplasm into the esophagus or may encircle the esophagus and constrict its lumen. In either case obstruction is a constant manifestation In some the tumor ulcerates and causes anemia, bleeding and early metastasis, and in these obstruction is late or absent.

Carcinoma of the distal part of the esophagus often metastasizes to the liver, the cardiac end of the stomach, the inferior mediastinum, the lungs and occasionally to the vertebrae. Carcinoma of the upper thoracic segment of the esophagus may spread to the trachea, and carcinoma of the upper third may invade the larynx, the pharynx, the thyroid or the recurrent laryngeal nerve.

The symptoms commence with a sensation of food sticking and stopping on its way down The sensation is attended by substernal or neck pain. After this symptom is established, there ensues a definite dysphagia The progress of the dysphagia is evident by the gradual elimination of solid food from the diet. In a few the first symptom appears after a foreign body has lodged in a narrowed, constricted esophagus and has been dislodged More commonly the patient has had what is described as an inability to get the food down Then regurgitation or vomiting ensues Hoarseness is an uncommon complaint It is due to paralysis of the recurrent laryngeal nerve or is the result of direct extension of carcinoma into the larynx.

A fistulous communication between the esophagus and the respiratory passages should be suspected from the onset of dyspnea and cough with the expectoration of blood, mucus and food Pulmonary abscesses, empyema and paralysis of a vocal cord rapidly ensue.

The physical examination rarely reveals more than evidence of loss of weight and pallor The degree of emaciation may be extreme. Occasionally lymph nodes may be palpated in the left supraclavicular, cervical, or axillary regions The liver may be enlarged. Frequently the swallowing sound on auscultation is delayed or absent

The diagnosis of carcinoma of the esophagus is based on endoscopic and roentgenoscopic examinations plus histologic examination of tissue removed for biopsy. Negative results of biopsy, however, do not exclude absolutely the diagnosis of a malignant lesion It may be necessary to perform biopsy two or more times in a case of suspected carcinoma before malignant tissue is found Compression of the esophagus from an extrinsic lesion may cause great difficulty in diagnosis

The innervation of the front and sides of the abdomen is supplied by the anterior and lateral cutaneous branches of the sixth, seventh, eighth, ninth, tenth and eleventh intercostal nerves, the twelfth thoracic and the iliohypogastric and ilio-inguinal branches of the first lumbar The sides of the abdomen are supplied by muscle branches

Besides the muscular innervation of the abdominal wall there is a connection of the cutaneous supply with that of the abdominal organs The areas of cutaneous hyperalgesia occurring in visceral disease are identical with the areas which receive their sensory nerve fibers from the spinal segment to which the afferent sympathetic fibers from the diseased viscera pass Head demonstrated that the sixth, seventh, eighth and ninth thoracic segments receive afferent fibers from the stomach, the ninth, tenth, eleventh and twelfth thoracic segments, from the intestinal tract, the seventh, eighth, ninth and tenth thoracic segments, from the liver and gallbladder, the tenth, eleventh and twelfth thoracic, and the first lumbar segment, from the kidneys and ureters; and the second, third and fourth lumbar segments from the rectum These areas of hyperalgesia occur, but to attempt to determine their presence subjects an ill patient to too great an ordeal to justify the meager diagnostic data obtained.

The Hernias. A hernia is a projection of a viscus or part through a natural or accidental opening in the wall of the cavity normally containing the viscus The term is qualified by the name of (1) the protruding part, (2) the cavity from which it escapes, (3) the structure or part through which it passes, and finally, sometimes, (4) the cavity which receives it A hernia therefore is a projection of a viscus from the cavity in which it naturally is contained, the lining membrane of the cavity being projected before it. This lining membrane will be referred to hereafter as the hernial sac or the sac

The abdominal cavity is completely surrounded by muscles. The bony support is posterior and caudal The contents of such a cavity are prone to herniation

VARIETIES When the projection is outward, beneath the skin or toward it, the hernia is external (subcutaneous, intermuscular or properitoneal), when within the body, in one of the larger body cavities, it is internal

The external hernias include (1) inguinal hernia, direct or indirect, (2) crural, or femoral, hernia, below Poupart's ligament, (3) umbilical hernia, (4) abdominal hernia, especially in the linea alba.

The internal hernias include (1) diaphragmatic hernia, recognizable in roentgenograms, (2) retroperitoneal hernias, (A) in Treitz's fossa, (B) in the recesses intersigmoideus and (C) in the foramen epiploicum of Winslow

When a hernia cannot be returned, but is fixed by adhesions or otherwise, it is said to be irreducible The most important complication is incarceration (not synonymous with irreducibility), which may lead to ileus and to strangulation

In investigating a case of suspected hernia, make a systematic examination as follows: (1) Does a hernia actually exist? (2) Is the hernia incarcerated? (3) What does the hernial sac contain? (4) What is the exact site of the incarceration?

TRAUMA AS A CAUSE OF HERNIAS. The physician is often asked for an opinion in regard to the effects of trauma as a causative agent of hernia

Acute traumatic hernia is rare Usually the condition develops gradually, owing to repeated strain beyond endurance of the weakened or abnormally patent inguinal rings or other natural or artificial openings due to congenital weakness of these structures or to weakness following surgical operation or injury The hernia in its incipient stage may exist for many months previous to being observed by the patient It can hardly be conceived that a hernia, inguinal or otherwise, can entirely and suddenly be brought about by severe strain unless there is a pre-existing formation of the mechanical changes such as the sac that produces the bulging It is possible, however, for such a pre-existing formation to become injured and as the result of such injury the individual's attention is for the first time called to abnormality of the region

However, in practice, in a particular instance of inguinal hernia, the hernia may

These tendinous intersections are the remains of the intersegmental septa which separate the original myotomes One is just above the umbilicus, a second *opposite the tip of* the ensiform cartilage, a third midway between these two, and sometimes there is a fourth below the umbilicus.

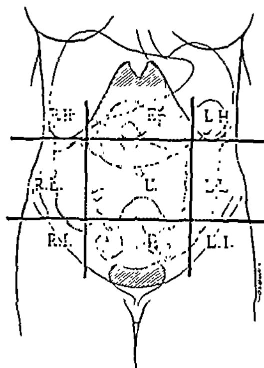

Fig 13-1 Topographic regions of the abdomen for precise description R H, right hypochondrium; R.L, right lumbar, R I, right inguinal, Ep, epigastrium, U, umbilical, P, pubic; L H, left hypochondrium, L.L, left lumbar, L I, left inguinal

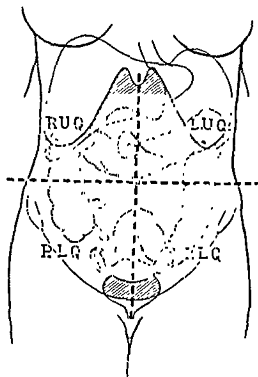

Fig. 13-2. Quadrants of the abdomen R U Q, right upper quadrant, R.L Q, right lower quadrant, L U.Q, left upper quadrant; L.L Q, left lower quadrant

Lineae albicantes are the faint, white, atrophic lines left in the skin of the abdomen after it has been hyperdistended, usually by pregnancy or tumors

The groove formed by Poupart's ligament runs from the anterior superior spine of the ilium to the spine of the pubis

The Abdominal Walls. The abdominal walls are composed of the skin, muscles and associated superficial and transversalis fasciae, blood vessels, lymphatics, and nerves.

The *skin* of the abdomen is moderately thin and lax It is adherent at the linea alba

The *muscles* of the abdomen are arranged in two distinct groups· a longitudinal group embracing the *recti* and *pyramidales* and a transverse group embracing the *external* and *internal oblique* and the *transversalis* of each side The abdominal muscles are rarely paralyzed.

The upper part of the abdomen is drained by small superficial veins which empty into the superior epigastric, the intercostal, and laterally into the axillary veins All the other abdominal veins drain into the inferior vena cava. When small veins around the umbilicus become enlarged and branch in various directions, the condition is termed *caput medusae*.

The superficial parts above the umbilicus are drained by *lymph vessels* which empty into the axillary nodes, the vessels below the umbilicus empty into the oblique set of nodes in the groin. The lymphatic channels of the deep surface of the abdominal wall above the umbilicus drain into the mediastinal nodes, while those below drain into the pelvic lymphatics along the iliac arteries

Inguinal hernia occasionally occurs in the female. There it presents itself at the inguinal canal or may follow the round ligament of the uterus into the labium majus pudendi The round ligament is homologous to the gubernaculum testis in the male.

There are two kinds of inguinal hernia, the *congenital* and the *acquired* and each of these may be indirect or direct. *Indirect* inguinal hernias are usually congenital, the degree being only a variation in the quantitative expression of a congenital defect existent at birth

The *direct* inguinal hernias may be the result of a developmental defect of the internal oblique and the transversalis muscles or more usually of the conjoined tendon, or they may be an acquired condition, the result of asthenia and debility

A direct inguinal hernia presents directly through the abdominal wall and not through the inguinal canal The hernia appears in the neighborhood of the external ring or may cause a protrusion of the abdominal wall just above and to the inner side of the ring

SYMPTOMS An inguinal hernia is observed by the patient as a protrusion or a mass in the groin It is accompanied by a moderate amount of pain during the first few days It may or may not be preceded by a history of undue strain The pain decreases, so that in a week or two the symptoms consist of nothing more than a feeling of discomfort

Frequently the history is given of the patient's having been examined by an industrial physician who found a dilated external ring and a transmitted impulse on

found if diligently sought for by the surgeon

EXAMINATION A precise method of physical examination for detection of the presence of hernias of the inguinal and the femoral regions has been outlined by Zieman

The patient is examined in the upright position with the examiner standing somewhat behind and to the right, using the right hand for a right inguinal hernia, and to the left, using the left hand for a left inguinal hernia This method in no way distorts the relationships of the parts in this region and it obviates a palpation artefact The examining hand is so placed that the first, second and third fingers lie over the inguinal region in such a manner that the index finger rests about 2 or 3 cm. above the inguinal canal. The middle finger lies along the direction of the inguinal canal with the tip of the finger at the external inguinal ring, while the third finger controls the femoral canal and the fossa ovalis With the hand in this position it is possible to perceive a distinct sliding, pushing motion of a viscus under one or another of the examining fingers when the patient is directed to cough or strain Thus a direct or an indirect inguinal hernia or a femoral hernia may become apparent If there is a bulging mass apparent to the eye, the examining hand forces the mass inward, and again coughing or straining immediately differentiates the type of hernia present The palpation of a bubbling mass which slides back into the abdomen determines the presence of a hernia

The usual method of examination for inguinal hernia is to pass the index finger along the spermatic card until the external inguinal canal is identified A bulging through the canal through which the impulse of a cough is transmitted indicates an inguinal hernia

DIAGNOSIS An inguinal hernia can hardly be confused with any other condition in these regions Enlargement of the inguinal or the femoral lymph nodes may resemble a hernia of the irreducible type. A lipoma over or in the inguinal canal presents a similar resemblance Acute inguinal lymphadenitis will usually be associated with pain and other inflammatory signs which, however, may also be demonstrable over a strangulated hernia The sudden development of symptoms accompanying strangulated hernia is usually sufficient to establish a correct diagnosis. Occasionally

be alleged to be of traumatic origin The patient relates a history of sudden pain in the groin associated with the appearance of a hernial mass immediately following a strain such as lifting. It should be stated that compensation boards usually consider trauma as being capable of producing hernias

Swelling from other causes may occur in the inguinal region and claim may be made of trauma as the cause. Gonorrheal and chancroidal bubo, epididymitis, and other infections and tumors may cause enlargement of lymph nodes in this region

Inguinal Hernias, Congenital and Acquired, Direct and Indirect. The *inguinal canal* (*canalis inguinalis*) runs from the external to the internal abdominal ring and is about 1¾ inches (4 5 cm) in length. The external ring barely admits the tip of the finger; it lies immediately to the outside and above the spine of the pubis. It is formed by a splitting of the fibers of the external oblique aponeurosis into two columns or pillars. The *internal column* (*crus superius*) inserts into the crest and anterior surface of the body of the pubis The fibers running across from one column to the other are the intercolumnar fibers (fibrae intercrurales) and are prolonged over the cord as the intercolumnar fascia

The internal ring (annulus inguinalis abdominalis) is the opening in the transversalis fascia where the spermatic cord in men and the round ligament of the uterus in women enters the canal

The body being upright, the inguinal canal has an anterior and a posterior wall, a roof and a floor It is ½ to ¾ inch (1.2 to 4.5 cm) long The anterior wall (nearest to the skin) is formed by the aponeurosis of the external oblique muscle and by the internal oblique muscle for its outer half The posterior wall is formed by the transversalis fascia and, at its inner third, the conjoined tendon The roof, toward the abdominal cavity, is formed by the arching fibers of the internal oblique muscle and, still farther above, the transversalis The *spermatic cord or round ligament* in the canal rests on Poupart's ligament

The foregoing anatomic structures were occasioned by the origin and descent of the *testicles* The testicle originates, about the third month of fetal life, in the lumbar region inside of the abdomen It is behind the peritoneum and has a fold of peritoneum, the plica vascularis, passing upward from it, containing the spermatic artery and veins, and a fold called the gubernaculum, passing downward to the inguinal region and into the scrotum. By the fifth or sixth month of fetal life the testicle has reached the abdominal wall at the internal ring, after which it enters the inguinal canal to pass into the scrotum *in the eighth or ninth month of fetal life. A process of peritoneum, the vaginal process,* precedes the passage of the testicle into the scrotum The neck of the vaginal process is called the funicular process Soon after birth the vaginal process becomes occluded, first at the internal ring, and thence downward until the testicle is reached, where the unobliterated portion forms the tunica vaginalis

During the descent of the testicles and the disposition of tissues which ensues, certain anatomic developmental defects may occur The resulting hernias are termed in accordance with their relationship to these defects vaginal (congenital), funicular, encysted, and infantile

In *vaginal hernia* the vaginal process remains entirely open and the intestine passes down into the scrotum The testicle is found protruding into and at the bottom of the hernial sac. In *funicular hernia* the vaginal process is occluded just above the testicle, but the funicular process remains open and the intestine descends into it If the vaginal process is occluded at the internal ring only, the remainder forms a continuous sac below containing the testicle. In *encysted hernia* the intestine descends and pushes the vaginal process before it down into the cavity containing the testicle. In *infantile hernia* also the vaginal process is occluded but only at the internal ring As the intestine descends, it forms a sac posterior to the point of occlusion and vaginal process

The *interparietal* (*interstitial*) *hernia* is a variety of oblique hernia It is often associated with anomalies of the testis It is so called because it does not emerge through the external ring, but presents itself through the layers of the abdominal wall.

the factor which prompted surgical intervention In every case reviewed, operation was performed

Intra-abdominal Hernias Referable to Congenital Malformations. Instances of congenital malformation of the primary midgut loop, excluding the duodenal hernia, have their origin in malrotations or improper fusion of the peritoneal layers, either of the mesentery of the small intestine, or of the cecum and the ascending part of the colon Persistent traction bands may also be found in such cases Defective disposition of the small intestines and right part of the colon, a process commonly termed malrotation, may account for hernias

Improper fusion of the peritoneal layers of the postarterial segment will result in the formation of small pouches under the cecum and ascending part of the colon. Retrocecal hernias are often found during the performance of surgical procedures for other conditions.

An internal hernia involving the mesentery of the small intestine may be present when prolapse of the bowel through an aperture lying between the ileocolic artery and its last mesenteric branch has taken place

The occurrence of internal herniation through the foramen of Winslow is extremely infrequent, because of the barrier afforded by the transverse part of the colon According to Mayo and Miller, one of the following factors must be present to permit the formation of this particular type of hernia: (1) A common mesentery for the whole intestine, (2) absence of secondary fusion of the ascending part of the colon to the abdominal wall, (3) an abnormally large foramen; and (4) an abnormal length of the mesentery and consequent marked mobility of the intestine In some instances a Meckel's diverticulum may remain attached to the abdominal wall, producing a bandlike structure These bands and adhesions are occasionally the cause of herniation, with resulting intestinal obstruction. Herniation into the prevesical space or the space of Retzius is rare

Postoperative Intra-abdominal Hernia. Intra-abdominal hernia, as a postoperative complication, may be immediate or delayed Failure of the transverse mesocolon to remain attached to the stomach following posterior gastroenterostomy may result in an aperture through which a loop of small intestine may slip into the lesser peritoneal sac and cause obstruction Hernias have been reported to afflict patients subsequent to resection of the stomach with anastomosis to the jejunum The presence of this type of hernia is difficult to recognize but in those cases in which gastrojejunostomy has been performed and symptoms of intestinal obstruction develop, or in which some mechanical defect in the anastomosis is present, the possibility of herniation must be considered Adhesive bands resulting from inflammation can form the opening through which the bowel may herniate These occur more commonly after various pelvic operations and secondary to operations for ruptured appendix

Subsequent to an operation for retroversion, some error in technic may occasionally be the cause of formation of an internal hernia In other instances, in performance of such operations as myomectomy, oophorectomy, appendectomy, and the like, openings are inadvertently made in the broad ligaments In the performance of other pelvic operations in which the uterus is suspended, instances of herniation of intestine between the uterus and the anterior abdominal wall have been recorded

Various apertures may occur in the omentum as a result of trauma or infection following operation

Paraduodenal Hernia. Many fossae about the duodenum have been minutely described, but proof that they are a factor in the causation of hernias with clinical manifestations is lacking

Left duodenal h[illegible]

[illegible] ıe contra-
[illegible] re usually
[illegible] explored

a psoas abscess may present in the inguinal region and produce a bulging mass which resembles a hernia.

Postoperative (Incisional, Ventral) Hernia. Suppuration of a wound in the abdominal wall is conducive to formation of hernia. Although hernia is likely to follow operation for drainage of intra-abdominal abscesses, for example, appendical abscess, only a few postoperative hernias are due to suppuration. Postoperative hernias occur most frequently in fat persons. Any pulmonary complication which results in frequent coughing during the first 5 or 6 postoperative days may produce a hernia, or even produce a rupture of the wound.

If the fatty subcutaneous tissue is thick, the hernial mass may burrow for a considerable distance subcutaneously The hernial opening often enlarges so that a large proportion of the contents of the abdominal cavity is eventually contained in the sac. The omentum becomes adherent to the sac, and if the sac becomes adherent to loops of intestine also, as it frequently does, the greater portion of the hernia may become irreducible

When the hernia first develops, the patient nearly always complains of a dragging pain arising in the neighborhood of the scar, but perhaps extending deep into the abdomen

Early in the formation of the hernia, tenderness at the site of the defect is pronounced When the hernia develops within a few days after laparotomy, because of partial rupture of the deep layers of the wound, the intestines herniating into the defect may at times become adherent and obstructed Usually, however, definite evidence of a hernia is not demonstrable, subjectively or objectively, for several weeks or months after operation

In some patients there is a general weakness of the abdominal wall which has developed postoperatively Such a weakness may permit of local bulging of the abdominal contents without actual herniation

The history, the reducibility, the impulse on palpation and particularly on coughing are unmistakable.

Intra-abdominal Hernia. Hernias that protrude into an abdominal pouch or opening of the peritoneum may be considered to be intra-abdominal or internal hernias These may be primary, a direct result of some congenital defect; secondary or postoperative sequelae, or referable to trauma or inflammation not the result of an operation. Thus, they include (1) those which occur in normal pockets, such as the foramen of Winslow, paraduodenal, paracecal, and intersigmoidal fossae; (2) those occurring in exaggerations of normal mesenteric folds, such as those in the broad ligament; (3) those resulting from traumatic or operative bands or adhesions; (4) those resulting from chronic inflammation, and (5) those which occur in anatomic defects.

A classification of internal hernias is difficult Intra-abdominal hernias have been classified by Mayo, Stalker and Miller into four groups. (1) congenital malformations, (2) postoperative, (3) paraduodenal and (4) miscellaneous

In the 39 cases reported by Mayo, Stalker and Miller, 21 (54 per cent) were considered to be secondary, and 18 (46 per cent) primary. In 20 instances the hernia developed secondarily, previous to performance of some surgical procedure

The symptoms presented by the hernias were, for the most part, varying degrees of intestinal obstruction In 29 cases (74 per cent) the hernia was considered to be producing symptoms, and in 10 cases (26 per cent) no symptoms were caused In the 10 cases in this latter group the hernia was observed incidentally at the time of operation for some other condition The symptoms, for the most part, were vague and not characteristic A preoperative diagnosis seldom was made Some degree of obstruction of the small intestine was present in 28 (72 per cent) of the cases. In 19 cases (49 per cent) the onset was marked with acute obstruction of the small intestine. When obstruction was not present, pain or the presence of a tumor was

syphilis of the umbilicus at or shortly after birth and (3) syphilis of the umbilicus in the adult.

The diagnosis is established by darkfield and serologic examinations and association with a proper history

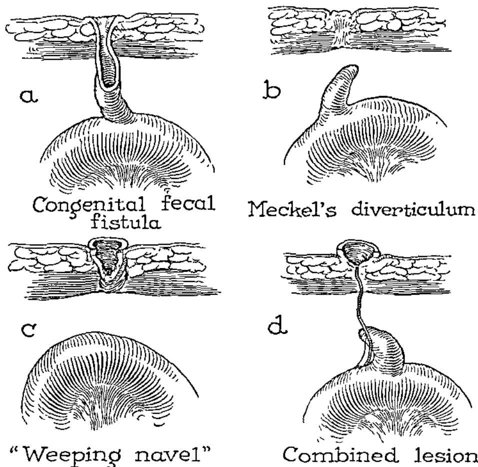

Fig 13-3 Schematic representation of varying degrees of persistent omphalomesenteric duct a, patent duct b, umbilical end obliterated with Meckel's diverticulum remaining c, the intestinal end obliterated but active mucous membrane situated in the umbilicus d, Meckel's diverticulum, persistent cord and mucous membrane in navel

Fecal Fistulas at the Umbilicus. Umbilical fistulas may be due to a patent omphalomesenteric duct, to inflammatory changes commencing in the intestine and extending to the umbilicus, to carcinoma of an abdominal organ, usually of the stomach, reaching to and breaking through the umbilicus, to inflammatory conditions of the umbilicus extending to and involving the intestine, and to external injuries

Umbilical Concretions Associated With Inflammatory Changes in the Abdominal Wall. In those who have umbilical concretions the umbilical opening

The pain may be increased on muscular exertion, on defecation, or on pressure upon the abdomen.

On visual examination sometimes nothing is detected Later, induration is noted

for other reasons. However, occasionally when obstruction, acute or chronic, or strangulation supervenes, the patients have symptoms

Miscellaneous Intra-abdominal Hernias. There are intra-abdominal hernias which cannot be satisfactorily classified Occasionally, *secondarily to some inflammatory* condition such as pelvic inflammatory disease or appendicitis *for which* surgical intervention was not performed, adhesive bands may form between which herniation or strangulation of the intestine may occur.

There are often present mesenteric and omental defects for which a cause cannot be assigned In the absence of a suggestive cause, many are thought to be of congenital origin. Rupture of the omentum or the mesentery as a result of external violence, or of injury during the course of a previous surgical operation, is considered to be possible cause in some instances In some cases, antecedent inflammation of the appendix with involvement and subsequent atrophy of mesentery or omentum may produce such a defect In the absence of both trauma and a previous operation these defects of the mesentery and omentum with subsequent hernia formation must be considered to be secondary to some congenital fault

Internal hernias become manifest through various degrees of intestinal obstruction, though some internal hernias are manifested by pain and formation of tumor.

The diagnosis of intra-abdominal hernia is seldom made prior to operation or postmortem examination.

Strangulated Hernia. *Strangulation does not develop until several hours after* the hernia becomes obstructed When strangulation develops, tension within the mass increases There is an increasing difficulty in reduction and soon reduction may become impossible Nausea and vomiting ensue The pain increases and becomes persistent The pain at first is poorly localized, but soon becomes most prominent in the mass, extending frequently into the depth of the abdomen. Prostration and a fast small pulse develop rapidly There may be mild collapse, with a cold, pale and moist skin, especially if a large amount of intestine is involved in the strangulation. The manifestations of intestinal obstruction ensue

On rare occasions strangulation may occur in an internal hernia The strangulation of an internal hernia is not diagnosed prior to operation In an occasional instance of strangulation of an internal hernia in an elderly patient the symptoms are ill defined and of a minimal degree and the diagnosis in such cases may be made at *postmortem examination*

THE UMBILICUS

The umbilicus varies widely in its location It is always in the midline of the abdomen but its cephalocereal level depends on the tone of the abdominal musculature and the quantity of the abdominal contents The vitelline duct in fetal life passes from the umbilical vesicle to the small intestine Normally it entirely disappears If its proximal extremity persists, it forms a Meckel's diverticulum (Fig. 13-3). If its distal end persists up to the umbilicus, there is a fistula through which feces may discharge If the lumen is obliterated, a fibrous cord may persist which may cause strangulation of the intestine The stalk of the allantois ends as the urachus, running down to the fundus of the bladder. If the urachus remains patulous, urine may be discharged through the umbilicus.

Infections of the Umbilicus. The umbilicus is singularly free of disease Low-grade umbilical infection and eczemas are common, however, and, ringworm, of the same species which *affects the intertriginous folds* of the body, occurs therein

Tuberculosis. Tuberculosis of the umbilicus is exceedingly rare It occurs when a tuberculous bowel becomes adherent to and opens through the umbilicus. The diagnosis is proved by guinea pig inoculations with biopsy or aspirated material from the umbilicus.

Syphilis. Syphilis of the navel is rare, but when it occurs, *it may be divided* into three groups for purposes of classification· (1) chancre of the u

contracts, a good deal of urine may be forced into the urachal pouch. In these cases the urine stagnates, decomposes, and constitutional symptoms ensue.

From time to time a tumor forms between the umbilicus and the pubes. This usually gives the patient considerable pain, and its presence is sometimes accompanied by fever.

The first manifestation usually is enlargement of the lower part of the abdomen in the midline, but the swelling, sometimes accompanied by pain, may first be observed in the right iliac fossa, and the symptoms may suggest appendicitis.

With the increase in abdominal girth, there may be a moderate degree of indigestion, and in some cases when the cyst has reached large proportions, dyspnea is present. Some of the patients become progressively emaciated and lose strength.

Micturition is normal in some, frequent in others The bladder may be encroached upon since the extent of the tumor is limited, on the one side by the peritoneum, and on the other by the anterior abdominal wall

Pain is a feature in some cases, absent in others The cyst is separated from the abdominal contents only by a thin peritoneum, and consequently the slightest inflammation of the cyst wall must extend to the peritoneum and produce pain and cause the omentum or some other abdominal structure to become adherent to the abdominal wall over the cyst

On physical examination an abdominal swelling is observed This may extend over the entire abdomen, or be limited to the lower portion. In some cases definite fluctuation can be elicited.

The diagnosis is usually obvious if the possibility of the condition is kept in mind Urachal cyst may resemble a distended bladder, ascites appendicitis with abscess formation, a cyst, localized peritonitis with a serous exudate under the anterior abdominal wall, and tuberculous peritonitis

Umbilical Hernias. Umbilical hernias are of three kinds, congenital, infantile and acquired

Congenital umbilical hernia is due to a developmental defect If development is interfered with, a cleft is left in the umbilical region into which intestine or other organs may protrude. If only intestine protrudes, it pushes up into the umbilical cord and constitutes a congenital umbilical hernia If the urachus remains patulous, it may form a urinary fistula The hypogastric arteries become obliterated and, opposite Poupart's ligament, have two fossae, one to their outside and one to their inside. Into these fossae direct inguinal hernias may pass The persistence of the vitelline duct may cause a finger-like projection, called Meckel's diverticulum, on the ileum, about 2 or 3 feet (61 0 or 91 4 cm) above the ileocecal valve Sometimes a band passes from Meckel's diverticulum to the umbilicus and causes strangulation of other coils of the intestine

Infantile umbilical hernia is the common form which appears soon after birth It does not contain omentum so constantly as does adult hernia, because it does not hang so low, nor is it so well developed

Acquired umbilical hernia is the form seen in adults The presence of the urachus and hypogastric arteries so strengthens the lower edge of the umbilical ring that hernial protrusions make their exit above, hence the hard edge of the ring is nearer the lower end of the umbilical hernial sac

The symptoms of umbilical hernia may appear either in infancy or in late adult life The first evidence of a hernia in childhood is evinced by a protrusion of the umbilicus when the child cries Such a hernia rarely produces any demonstrable symptoms Occasionally these hernias may enlarge until intestine also protrudes into the sac

Umbilical hernias in adults occur usually in the latter part of life and are three or four times more common in women than in men Relaxation of the abdominal muscles during pregnancy and obesity seems to be important. The skin over the hernia is thin and often bluish in color The subcutaneous tissue is often absent between the thin skin and the contents of the sac The symptoms of umbilical hernia

in the umbilical region, the umbilical opening becomes very small, and the surrounding tissue feels hard. The overlying skin may or may not be reddened. At this stage the patient may have excruciating abdominal pain, followed by the escape of a foreign body together with some blood and pus. A speedy disappearance of the symptoms usually follows.

Occasionally an umbilical concretion may be present without producing any inflammatory reaction

The Escape of Various Foreign Substances From the Umbilicus. Gallstones. The patients as a rule give the usual history of gallstones. Sometimes the initial pain is in the gallbladder region, but occasionally it is first noted in the left side of the hypochondrium, after a time it shifts to the right side In addition to the hepatic colic noted, there are sometimes nausea, vomiting, and diarrhea After a varying length of time, changes may be noted at the umbilicus. Abscess formation progresses rapidly, the stones are evacuated when the abscess is lanced or may be discharged spontaneously

Roundworms. The majority of the patients have symptoms of a gastrointestinal disturbance After a period varying from a few days to a couple of weeks soreness develops at the umbilicus, the center of the umbilicus gradually becomes softened, and the surrounding portions are thickened and edematous

In the course of a few days the abscess breaks and there is an escape of pus Sometimes this is accompanied by fecal matter or roundworms or both; occasionally fecal matter is not detected at all, the wound closing up after the pus and worms have escaped The worms may be alive or dead Occasionally only one worm escapes but, as a rule, several come away at once Closure of the wound may occur temporarily, only to be followed by more pain and the expulsion of more worms

The Urachus. Urachal remains occasionally communicate with the umbilicus or with the bladder or with both (Fig 13-4) There is usually a history of vesical

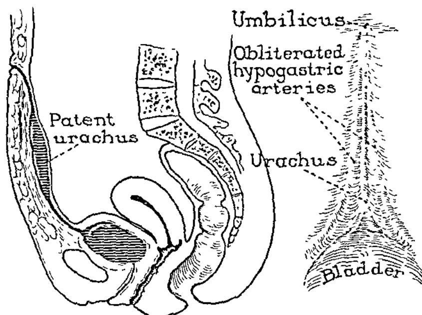

Fig. 13-4 Schematic representation of persistent urachus

irritability, and from time to time pus is passed with the urine. Sometimes the urachus is in reality an alcove from the bladder, the opening being very wide and assuring complete emptying of the cavity each time the bladder is evacuated On the other hand, if the communicating opening is very small, whenever the bladder

wounds in the abdomen and from the rupture of normal graafian follicles, and the peritonitis occurring in the course of septicemia and following surgical operation.

SYMPTOMS Acute peritonitis commences with generalized abdominal pain which is intense and is aggravated by movement and pressure The patient, if physically able, assumes a position which relieves the tension of the abdominal muscles. The usual position assumed is flat on the back, with the thighs drawn up and the shoulders elevated The patient desires to be left alone and is definitely annoyed by questions and examinations He is apprehensive and mentally preoccupied. The most intense pain usually is below the umbilicus except that in peritonitis from perforation of the stomach, duodenum or gallbladder the pain may be in the epigastrium and it is often referred to the back, thorax or shoulders

Respiration is superficial, costal and painful. Coughing is restrained In contrast to the foregoing symptoms an occasional patient may have an acute peritonitis, with a limited amount of pain, or the pain may be absent.

Vomiting is an early and prominent symptom and causes the patient a great deal of pain and discomfort As the disease progresses, the vomitus begins to be a brownish or black liquid When the sensorium is dulled by fever, there may be no symptoms indicating the onset of the peritonitis

EXAMINATION The abdomen is very tender and the muscles are rigid. The abdomen soon becomes distended and tense, and tympanitic, and respiratory movement in the abdomen is absent The pulse is rapid, small, hard and often has a quick rebound (pulsus celer). The pulse rate varies from 100 to 150. The rate usually increases as the disease progresses. After 24 to 48 hours the temperature may recede somewhat and remain at from 101 to 102 F (38 3 to 38 8 C) until near the end In acute peritonitis in an enfeebled patient there may be diminished pain and few systemic reactions, and there may be no fever

A group of signs designated as rebound phenomena includes rebound tenderness. Rebound tenderness is induced by sudden release of a pressure of the hand firmly applied to the abdomen The rebound phenomena also include pain induced on walking or by sudden flexion of one thigh, pain experienced on inward rotation of the leg, and pain produced on coughing

When the abdomen is auscultated, peristaltic noises are not present; an occasional tinkle of a bubble of gas in the intestine may be heard. The heart and the voice sounds are usually freely transmitted to the abdomen Vocal fremitus is often transmitted to all parts of the abdomen Usually the diaphragm is elevated and the hepatic dullness may disappear As the disease progresses, there may be effusion of fluid into the peritoneal cavity

A patient may have acute generalized peritonitis; in two hours the peritonitis may have begun to be localized, and thus the signs may change into those of localizing peritonitis If localization of acute peritonitis does not take place, the disease is rapid in its progress and usually is fatal

Acute secondary peritonitis always tends to *localize*, thus giving the symptoms of an abscess in the vicinity of its localization However, localized or circumscribed peritonitis may change into acute generalized peritonitis

The symptoms of localized peritonitis depend on the situation of the infected organ which is producing the peritonitis Since localizing peritonitis more often is produced by appendicitis or pelvic abscess than by other causes, it is most frequently situated in the right iliac fossa and in the pelvis

In women the commonest causes of pelvic peritonitis are puerperal septicemia, gonorrhea and tuberculosis of the internal genitalia In these conditions there are signs of a localized peritonitis or abscess in the pelvis.

DIAGNOSIS The diagnosis of a generalized, or a localized, primary or secondary acute peritonitis depends on obtaining the history and observing the afore-mentioned findings

in adults may not be pronounced The development of cramping pain, nausea and, especially, vomiting, indicates partial or complete intestinal obstruction. On account of the thin skin and the protrusion of the mass, the skin becomes traumatized readily and ulceration may develop. As the duration of the hernia increases, irreducibility becomes more pronounced Strangulation is uncommon

DIAGNOSIS The diagnosis is usually obvious. Lipoma of the umbilical region may have to be differentiated.

Tumors of the Umbilicus. Cullen listed both benign and malignant tumors of the umbilicus. There are both primary and secondary malignant tumors. The secondary malignant tumors which are secondary to intra-abdominal malignant disease are the commonest of all tumors of the umbilicus.

The benign tumors include (1) hypertrophy of the umbilicus; (2) angiomas; (3) lymphoceles; (4) benign connective tissue growths, (a) myxomas, (b) fibromas, (c) papillomas and (d) lipomas The ordinary umbilical papilloma is caused by a proliferation of the stroma, the squamous epithelium covering the papillae occupies merely a passive role It is for this reason that these small tumors are grouped with the benign connective tissue growths There are also (5) dermoid cysts; (6) sweat gland tumors; (7) abdominal myomas springing from the umbilicus, (8) papillomas secondary to growth in an ovary; and (9) adenomyomas

Malignant tumors of the umbilicus include carcinoma, primary and secondary, and sarcoma.

Primary carcinoma is of two types (1) squamous cell carcinoma and (2) adenocarcinoma. *Secondary carcinoma* arises (1) from the stomach, (2) from the gallbladder, (3) from the intestine, (4) from an ovary, (5) from the uterus and (6) from other abdominal organs

Sarcoma is classified as (1) telangiectatic myxosarcoma, (2) spindle cell sarcoma, (3) round cell sarcoma and (4) melanotic sarcoma.

THE PERITONEUM

Peritonitis. The peritoneum, pleura, and pericardium are derived from the celomic cavity The reactions of these structures to infections are analogous The entrance of an infecting agent into the pericardial, the pleural, or the peritoneal cavity is followed immediately by a heavy outpouring of exudates In all, there is a tendency to form fibrinous adhesions in an attempt to localize the infecting process

The peritoneal cavity, because of its close relation to the liver, gall ducts, gallbladder, spleen, kidneys, ureters, urinary bladder, and, in women, internal genitalia, is liable to infection from diseases of these organs Infection of the peritoneal cavity is termed peritonitis Peritonitis is referred to as being present in the acute, localized, and chronic forms

Acute Peritonitis. Acute peritonitis may be either a primary or a secondary infection of the peritoneum

Acute primary peritonitis arises from the organisms, most frequently pneumococci, streptococci, or *Mycobacterium tuberculosis,* reaching the peritoneum by way of the blood or the lymph An *acute primary peritonitis* often occurs in infant girls, and in this form of the disease the pyogenic organism probably reaches the peritoneum through the genital tract Acute primary peritonitis is frequently observed as a terminal event in nephritis, arteriosclerosis with renal insufficiency, gout and other chronic diseases. This type of peritonitis may be associated with a terminal pneumonia and also in some instances with a pericarditis

Acute secondary peritonitis results from an extension of inflammation from the perforation of a hollow viscus which is covered by the peritoneum, such as the appendix, stomach and intestine, or from acute suppurative inflammation of the spleen, liver, pancreas, retroperitoneal tissues and pelvic viscera In this group of infections of the peritoneum is included the peritonitis which results from penetrating

wounds in the abdomen and from the rupture of normal graafian follicles, and the peritonitis occurring in the course of septicemia and following surgical operation.

SYMPTOMS Acute peritonitis commences with generalized abdominal pain which is intense and is aggravated by movement and pressure. The patient, if physically able, assumes a position which relieves the tension of the abdominal muscles. The usual position assumed is flat on the back, with the thighs drawn up and the shoulders elevated The patient desires to be left alone and is definitely annoyed by questions and examinations. He is apprehensive and mentally preoccupied The most intense pain usually is below the umbilicus except that in peritonitis from perforation of the stomach, duodenum or gallbladder the pain may be in the epigastrium and it is often referred to the back, thorax or shoulders.

Respiration is superficial, costal and painful Coughing is restrained In contrast to the foregoing symptoms an occasional patient may have an acute peritonitis, with a limited amount of pain, or the pain may be absent

Vomiting is an early and prominent symptom and causes the patient a great deal of pain and discomfort As the disease progresses, the vomitus begins to be a brownish or black liquid When the sensorium is dulled by fever, there may be no symptoms indicating the onset of the peritonitis

EXAMINATION The abdomen is very tender and the muscles are rigid. The abdomen soon becomes distended and tense, and tympanitic, and respiratory movement in the abdomen is absent The pulse is rapid, small, hard and often has a quick rebound (pulsus celer) The pulse rate varies from 100 to 150. The rate usually increases as the disease progresses After 24 to 48 hours the temperature may recede somewhat and remain at from 101 to 102 F (38 3 to 38 8 C) until near the end In acute peritonitis in an enfeebled patient there may be diminished pain and few systemic reactions, and there may be no fever

A group of signs designated as rebound phenomena includes rebound tenderness Rebound tenderness is induced by sudden release of a pressure of the hand firmly applied to the abdomen The rebound phenomena also include pain induced on walking or by sudden flexion of one thigh, pain experienced on inward rotation of the leg, and pain produced on coughing

When the abdomen is auscultated, peristaltic noises are not present, an occasional tinkle of a bubble of gas in the intestine may be heard The heart and the voice sounds are usually freely transmitted to the abdomen Vocal fremitus is often transmitted to all parts of the abdomen Usually the diaphragm is elevated and the hepatic dullness may disappear As the disease progresses, there may be effusion of fluid into the peritoneal cavity

A patient may have acute generalized peritonitis, in two hours the peritonitis may have begun to be localized, and thus the signs may change into those of localizing peritonitis If localization of acute peritonitis does not take place, the disease is rapid in its progress and usually is fatal

Acute secondary peritonitis always tends to *localize*, thus giving the symptoms of an abscess in the vicinity of its localization However, localized or circumscribed peritonitis may change into acute generalized peritonitis

The symptoms of localized peritonitis depend on the situation of the infected organ which is producing the peritonitis Since localizing peritonitis more often is produced by appendicitis or pelvic abscess than by other causes, it is most frequently situated in the right iliac fossa and in the pelvis

In women the commonest causes of pelvic peritonitis are puerperal septicemia, gonorrhea and tuberculosis of the internal genitalia In these conditions there are signs of a localized peritonitis or abscess in the pelvis

DIAGNOSIS. The diagnosis of a generalized, or a localized, primary or secondary acute peritonitis depends on obtaining the history and observing the afore-mentioned findings

Subdiaphragmatic Abscess. In 3 of every 4 instances collection of pus *under* the diaphragm is due to rupture of an abdominal viscus, or soiling of the *peritoneum* during surgical operation. In 1 of every 6, there has been an *extension from an* adjacent abscess, such as a perinephritic abscess. In the remainder the *infection* is blood borne from a distant focus In about one third of the cases the abscess *follows* appendicitis and in from one fourth to one fifth of the cases the abscess has developed subsequent to perforation of a peptic ulcer

Pleural effusion of clear sterile fluid on the affected side is the commonest associated lesion of a subdiaphragmatic abscess

SYMPTOMS. Subphrenic or subdiaphragmatic abscess following surgical operation or perforation of a viscus is considered if symptoms suggesting a *severe infection* appear from 4 to 10 days after the perforation or operation. Usually the first symptoms are a rise in temperature, hiccough and a gradually increasing toxemia Pain may be present on the affected side in the thorax or in the upper part of the abdomen. Shoulder tip pain is not often complained of by the patient. Its presence *may* be admitted. Deep breathing accentuates the shoulder tip discomfort.

EXAMINATION On inspection, fullness of the intercostal spaces over the suspected lesion rarely is detectable Some bulging of the lower part of the thorax and limitation of thoracic motion on the diseased side may be present if the collection of pus is large An abscess in the left anterior fossa may cause a visible prominence below the left rib margin anteriorly and a smooth tender tumor may be palpable in that region In subphrenic collections of pus, jarring of the lower part of the thoracic cage may produce severe pain

On percussion, dullness is present at the base of the lung on the affected side because of elevation of the diaphragm. Hepatic dullness may extend as high as the *third or fourth interspace anteriorly or into the axilla. Diminished or absent* breath sounds together with impaired tactile and vocal fremitus are often present at the base of the lung There may be a friction rub In some hyperresonance may extend below the costal margin.

If gas and pus are present in the abscess, the breath sounds and voice sounds are amphoric.

DIAGNOSIS. The diagnosis of a subdiaphragmatic abscess requires a knowledge of the history, the physical findings and roentgenologic examination A neutrophilic leukocytosis is revealed in the beginning of the infection if the patient's resistance remains good

Chronic Peritonitis. Since tuberculous peritonitis is so common, the criteria for diagnosis of chronic peritonitis are based largely on the presence or the absence of symptoms which may occur in this disease. However, there are, no doubt, many low-grade forms of chronic peritoneal infection which are evidenced by the presence in the abdomen of adhesions or fibrous bands which are not of *tuberculous* origin There may or may not have been symptoms of peritonitis These adhesions do not produce symptoms unless they are so situated that they interfere with the passage of the alimentary material through the lumen of the gut. In other words, unless adhesions or fibrous bands can produce obstruction of the intestine, other causes for abdominal symptoms should be sought.

Tuberculous Peritonitis. Tuberculous peritonitis occurs in adolescence or early adult life The disease in children before puberty attacks the sexes equally. Among children less than 2 years of age the disease is rare, and among persons more than 40 years of age the incidence again diminishes After this period the greater incidence is among women. Tuberculous peritonitis may be either acute or chronic.

In the severe forms of acute tuberculous peritonitis there are fever, chills, sweats, tachycardia and cyanosis These symptoms may be so severe that the *peritoneal* involvement is not appreciated unless the abdominal distention becomes *prominent* In the less severe acute stage of tuberculous *peritonitis the disease* commences *with*

generalized abdominal pain, nausea, vomiting, gaseous distention and a rapid accumulation of ascites.

When there is an active tuberculous focus in the abdomen or pelvis, such as a tuberculous mesenteric lymph node, a tuberculous intestine or a tuberculous uterine tube, at first there may be symptoms of localized peritonitis in the region of the infected part Then there may appear an acute abdominal condition which may indicate a miliary involvement of the peritoneum The symptoms of these miliary tuberculous processes extending from a primary focus in the abdomen are such that an acute secondary peritonitis is suspected After the acute symptoms subside, plastic masses of adherent and thickened intestine form and become palpable. The clinical course is then subacute or chronic, with remittent fever, sweats and emaciation

The commonest source of chronic tuberculous peritonitis appears to be tuberculous mesenteric nodes—the so-called tabes mesenterica The bovine strain of the tubercle bacillus is the usual offender in cases of tabes mesenterica.

The *pathologic changes* in the peritoneum are comparable to those of the pleurae when infected by tubercle bacilli. Just as there are a dry form and a wet form of pleurisy, there are the dry and the wet forms of peritonitis In association with the latter there is marked ascites. Examination of the peritoneal surfaces reveals the presence of tubercles In the dry form there is little effusion, but the peritoneal surfaces are adherent in places

The *symptoms* may comprise high fever and abdominal pain varying in intensity; occasionally there is a friction rub on respiration in a patient who has the dry form of the disease Despite widespread adhesions and fibrosis, intestinal motility is maintained well Intestinal obstruction does occur, but is not common

Examination will reveal that the patient is often emaciated The abdomen has been described as having a doughy feel The intestines may be matted together in a palpable mass The omentum may be thickened and drawn together by fibrosis to form a thick mass, which is palpable and may resemble a true neoplastic process.

Leukocytosis varies Often there is a slight increase in the total count, but polymorphonuclear leukocytosis is not present

If the intestinal lumen is deformed by an active tuberculous process, the roentgenologic examination may reveal characteristic changes which will establish the *diagnosis* In the absence of active tuberculous foci elsewhere, it may be necessary to perform surgical exploration to establish the diagnosis Some physicians use peritoneoscopy as a diagnostic procedure An exploratory operation is of low risk to the patient and has the advantage of obtaining tissue so that a definite diagnosis can be made by histologic study and by cultural means

Diseases of the Peritoneum Due to Higher Animal Parasites. Echinococcus disease of the peritoneum occurs as a part of this generalized infection There are present multiple abdominal tumors. The diagnosis of the disease is rarely made prior to surgical exploration and biopsy, or necropsy Rarely are the cystic forms of other worms observed

Tumors of the Peritoneum. Primary tumors of the peritoneum are rare. Metastatic tumors of the peritoneum are common in association with the terminal stages of cancer of the intraperitoneal organs Carcinomas of the ovaries and the stomach, colon and rectum are specially prone to cause widespread tumors on the peritoneal surfaces Often, when metastatic tumors are present in the peritoneum, ascites is present

Little can be done for patients who have metastatic tumors of the peritoneum Abdominal paracentesis may offer the only chance for temporary relief.

THE MESENTERY

Congenital Anomalies of the Mesentery. The normal distribution and position of the mesentery depend on the normal development of the intestines, rotation during embryonic life, and fixation or anchoring of the fully developed intestine. A total failure

Subdiaphragmatic Abscess. In 3 of every 4 instances collection of pus under the diaphragm is due to rupture of an abdominal viscus, or soiling of the peritoneum during surgical operation. In 1 of every 6, there has been an extension from an adjacent abscess, such as a perinephritic abscess. In the remainder the infection is blood borne from a distant focus. In about one third of the cases the abscess follows appendicitis and in from one fourth to one fifth of the cases the abscess has developed subsequent to perforation of a peptic ulcer.

Pleural effusion of clear sterile fluid on the affected side is the commonest associated lesion of a subdiaphragmatic abscess

SYMPTOMS Subphrenic or subdiaphragmatic abscess following surgical operation or perforation of a viscus is considered if symptoms suggesting a severe infection appear from 4 to 10 days after the perforation or operation. Usually the first symptoms are a rise in temperature, hiccough and a gradually increasing toxemia. Pain may be present on the affected side in the thorax or in the upper part of the abdomen. Shoulder tip pain is not often complained of by the patient Its presence may be admitted Deep breathing accentuates the shoulder tip discomfort.

EXAMINATION On inspection, fullness of the intercostal spaces over the suspected lesion rarely is detectable Some bulging of the lower part of the thorax and limitation of thoracic motion on the diseased side may be present if the collection of pus is large An abscess in the left anterior fossa may cause a visible prominence below the left rib margin anteriorly and a smooth tender tumor may be palpable in that region. In subphrenic collections of pus, jarring of the lower part of the thoracic cage may produce severe pain

On percussion, dullness is present at the base of the lung on the affected side because of elevation of the diaphragm. Hepatic dullness may extend as high as the third or fourth interspace anteriorly or into the axilla Diminished or absent breath sounds together with impaired tactile and vocal fremitus are often present at the base of the lung There may be a friction rub In some hyperresonance may extend below the costal margin.

If gas and pus are present in the abscess, the breath sounds and voice sounds are amphoric

DIAGNOSIS The diagnosis of a subdiaphragmatic abscess requires a knowledge of the history, the physical findings and roentgenologic examination A neutrophilic leukocytosis is revealed in the beginning of the infection if the patient's resistance remains good

Chronic Peritonitis. Since tuberculous peritonitis is so common, the criteria for diagnosis of chronic peritonitis are based largely on the presence or the absence of symptoms which may occur in this disease However, there are, no doubt, many low-grade forms of chronic peritoneal infection which are evidenced by the presence in the abdomen of adhesions or fibrous bands which are not of tuberculous origin There may or may not have been symptoms of peritonitis. These adhesions do not produce symptoms unless they are so situated that they interfere with the passage of the alimentary material through the lumen of the gut In other words, unless adhesions or fibrous bands can produce obstruction of the intestine, other causes for abdominal symptoms should be sought.

Tuberculous Peritonitis. Tuberculous peritonitis occurs in adolescence or early adult life The disease in children before puberty attacks the sexes equally. Among children less than 2 years of age the disease is rare, and among persons more than 40 years of age the incidence again diminishes After this period the greater incidence is among women Tuberculous peritonitis may be either acute or chronic

In the severe forms of acute tuberculous peritonitis there are fever, chills, sweats, tachycardia and cyanosis. These symptoms may be so severe that the peritoneal involvement is not appreciated unless the abdominal distention becomes prominent In the less severe acute stage of tuberculous peritonitis the disease commences with

rarely attain a large size They tend to occur multiply. Mesocolic cysts are lined with endothelial cells and contain light yellow-colored fluid, and these may occur multiply Dermoid cysts may attain great size. They maintain their usual characteristics when present in the mesentery They usually occur singly.

The symptoms do not commence until the cyst is large enough to give pressure on, or obstruction to, the intestine In large cysts the appearance of a mass may be the only complaint In some instances the first symptom may be an acute abdominal emergency, such as intestinal obstruction, or volvulus, precipitated by the tumorous growth.

There is a tumor in the abdomen Rarely can fluctuation in the mass be obtained. The mobility of the tumor varies; some are highly mobile while others are ill defined in outline and of limited movement in the abdomen.

[illegible]

operation The diagnosis of most mesenteric cysts is uncertain prior to surgical operation or necropsy

Solid Tumors of the Mesentery and Retroperitoneal Space. The solid tumors of the mesentery and retroperitoneal space may be either benign or malignant, and their variety is equal to the number of different types of connective tissue present in the mesentery and in the structures in and about the root of the mesentery and in the peritoneal regions

Lipomas or myxomas are the commonest solid tumors arising in the mesentery and are often multiple It may be difficult to determine whether fibromas and fibromyomas are extra-intestinal or arise from the bowel between the leaves of the mesentery. The malignant lymphomas, often of the Hodgkin type, are the commonest solid tumors arising in the retroperitoneal spaces.

Other tumors which frequently are found within the mesentery are metastatic growths, either carcinomas or those of the lymphoblastoma group, which includes Hodgkin's disease

There are no characteristic manifestations A tumor may or may not be palpable on examination. In Hodgkin's disease there may be fever of the Pel-Ebstein type and often superficial lymph nodes from which biopsy studies may be made. The solid tumors are diagnosed as tumors of the mesentery or retroperitoneal spaces on direct examination by the pathologist or surgeon

The prognosis depends on the type of tumor Benign tumors, particularly the lipomas of the mesentery, have a great tendency to recur

THE OMENTUM

The omentum varies greatly in size and, if large enough, is often at the site of intra-abdominal pathologic change, but its presence there is the result of being displaced from its usual resting place, the displacement having been initiated by such forces as peristalsis, diaphragmatic excursions, and changes in posture of its owner. Once the omentum is at the site of infection or injury, it may become adherent to the diseased tissue and become palpable

Diseases of the Omentum Due to Prenatal Influences. The congenital defects of the omentum comprise omental bands and omental cysts

[illegible]

part

of th

bands cause any symptoms, they are the result of angulation, trauma, and perhaps intestinal obstruction at these points.

In rare instances intestinal obstruction may have been present intermittently since childhood or since regular ingestion of a diet containing solid foods.

of fixation of the intestine permits excessive motility of the bowel, which may twist about the root of the mesentery, producing volvulus and obstruction. Segments of the mesentery may be long while others are short Both long and short mesenteries may be implicated in intestinal volvulus.

The primitive cavity of the omental bursae sometimes is not fully obliterated during prenatal life. In these instances the inferior recess may extend to the caudal end of the greater omentum.

Infections of the Mesentery. Mesenteric Lymphadenitis. This is an inflammation and enlargement of the mesenteric lymph nodes of the ileocecal region, the cause of which is unknown

The presence of soft, swollen, inflamed nodes in the ileocecal region may be accompanied by an increased amount of peritoneal fluid. On rare occasions the nodes may suppurate, and when this occurs, the findings are similar to those in cases of appendical abscess except for the fact that the appendix is normal

The disease usually occurs before adult life and is seen with increasing frequency after the third year. The symptoms consist of pain usually situated, and remaining, in the right lower quadrant of the abdomen Nausea is frequent; vomiting may occur Diarrhea is frequently present The physical examination does not reveal tenderness and the muscle rebound phenomenon There is often fever Leukocytosis may be increased out of proportion to the physical findings.

Appendicitis is usually the preoperative diagnosis. There is one important distinguishing feature between this disease and appendicitis· It is rare for the patient who has appendicitis to have diarrhea Constipation is the rule in appendicitis. However, acute appendicitis cannot always be excluded and therefore the correct diagnosis is made at surgical operation

The prognosis is uncertain. Symptoms may continue for a long time Eventual recovery is expected

Tuberculosis of the Mesenteric Lymph Nodes. This disease affects the two sexes with equal frequency.

Tuberculosis of the abdominal lymph nodes is often associated with tuberculous enteritis and frequently is fatal in infants and children In some patients this form of tuberculosis runs a mild course Often, when calcification of the lymph nodes is found later in life, there is no history to suggest that a tuberculous adenopathy was ever present. In those who have recovered from the disease, the calcified nodes remain in the mesentery and may interfere with the interpretations of intravenous pyelography at a later date

The ileocecal nodes are usually affected In an active tuberculous infection there are caseous nodes in the mesentery The extent of lymph-node involvement is more extensive in the presence of ulceration of the intestine by tubercle bacilli

The symptoms commence with pain situated in the middle of the abdomen The pain recurs two or three times a day and stops as suddenly as it starts Between attacks there is comfort The pain is generalized, but if unilateral, is more severe on the right side than on the left These symptoms recur at irregular intervals There may be nausea, vomiting, and constipation Physical examination does not reveal characteristic findings There may be tenderness in the right iliac fossa

The diagnosis is usually made at necropsy, or on biopsy of a lymph node removed at the time of an exploratory laparotomy. However, in those in whom there are no other serious foci, the prognosis is good

Cysts of the Mesentery. Aside from the cysts of parasitic origin (echinococcus), mesenteric cysts are largely of congenital origin They may be enumerated as (1) enterocystomas; remnants of the normal diverticula of the intestines pinched off from the intestines at an early embryonic age, (2) chylous cysts (lymphangioma cavernosum), (3) mesocolic cysts and (4) dermoid cysts.

Enterocystomas are lined with epithelial cells similar to the lining cells of the adjacent gut. They are the commonest mesenteric cysts Chylous cysts are small and

(atherosclerosis) and (4) mycotic aneurysms resulting from septicemias Periarteritis nodosa usually does not involve large arterial trunks. Trauma is rarely a cause of an aneurysm of the aorta.

Aneurysms of the descending aorta in those past 45 years of age are considered generally to be predominantly arteriosclerotic, syphilis being responsible for only 9 per cent in the series of abdominal aneurysms reported by Mills and Horton. However, in patients less than 45 to 50 years of age, among whom there are more Negroes than whites, syphilis is responsible for more than one half of abdominal aneurysms. Arteriosclerotic abdominal aneurysm occurs predominantly in those more than 60 years old and almost never before 45 years of age. The syphilitic aneurysm usually occurs at the level of the celiac axis

Aneurysms of the descending aorta may reach immense size and may almost completely fill the thoracic cavity or the abdomen before they produce symptoms. If the aneurysm arises in the thorax, there may be a huge thoracic mass discovered on roentgenologic examination of a patient who has complained of few or no symptoms If manifestations of aneurysms in the thoracic cavity are present, they consist of thoracic pain, dyspnea and cough. Dysphagia is an occasional symptom resulting from pressure on the esophagus There is a visible pulsation on the posterior thoracic wall either below and to the left of the left scapula or somewhat higher in the interscapular region

If the aneurysm of the aorta is situated within the abdominal cavity, it is manifested by pain in the abdomen and the back The pain may be paroxysmal, or constant and boring There may be root pains extending from the back to the upper part of the abdomen These and other symptoms result from erosion of the vertebrae and pressure on the spinal cord, gastrointestinal tract, ureter or other abdominal structures. Death is usually caused by rupture of the sac into the peritoneal cavity, gastrointestinal tract or retroperitoneal space. In the experience of Estes only one third of those who have abdominal aneurysms have symptoms at the time the diagnosis is made or suspected

The diagnosis is established by the presence of a pulsating expansile abdominal tumor. The roentgenologic and roentgenoscopic examinations confirm the impression gained by physical examination. The roentgenologic examinations reveal opaque shadows caused by atheromatous plaques throughout the mass. Aortography is a precise diagnostic procedure.

Aneurysm of a *renal artery* etiologically has the same origin as aneurysms of the thoracic and abdominal aortas The so-called *false aneurysm* results from trauma to the renal artery, a vessel which may have been weakened by a congenital fault The cardinal symptoms of false aneurysm are hematuria, pain and tumefaction in the flank. Pulsation and a systolic bruit may be present The presence in the roentgenogram of a ringlike shadow in the renal region, with a dense periphery disrupted in one portion and a rarefaction of the center, is suggestive of aneurysm of a renal artery

A *true aneurysm* of a renal artery is usually asymptomatic. It is found by palpation of the abdomen If symptoms are present, they arise from pressure or from pain which may have the characteristics of renal colic. On examination a palpable, expansile, pulsating mass may be present The diagnosis is established by roentgenologic methods However, aneurysms of the renal arteries usually are not diagnosed prior to surgical exploration or prior to death.

Aneurysm of the *splenic artery* usually is not diagnosed prior to operation or to death The aneurysm usually is asymptomatic until the time of rupture. Before rupture there are complaints which vary from mild epigastric pain to more severe abdominal complaints which may suggest gallbladder disease or peptic ulcer Pressure of the aneurysm on the pancreas may cause insufficiency of the external secretions of the pancreas manifested by steatorrhea. The spleen is palpable owing to infarction. In some, a pulsation may be felt or a bruit heard in the left upper part

The diagnosis is made at the time of surgical exploration of the abdomen or at necropsy.

Omental Cysts. A great many omental cysts, including dermoid cysts, are no doubt of congenital origin. The source of the rest of them is obscure.

Intestinal obstruction or torsion of the omentum may occur in association wit omental cysts. In large cysts, abdominal tumor is present. In such cases ascites ma be impossible to differentiate.

Cysts are diagnosed clinically as abdominal tumors. The nature of the tumo awaits direct inspection Discovery by roentgenologic examination of the presence o *calcium in the cyst may suggest the diagnosis Dermoid cysts are definitely diagnose* roentgenographically

Cysts of the mesentery and peritoneum, cysts of the retroperitoneum, splenic hepatic and renal tumors, and aneurysm may not have any clinical differential diag nostic features from those of omental cysts.

Diseases of the Omentum Due to Trauma or Physical Agent. *Torsion of the Omentum.* Omental torsion occurs on the long axis of the omentum The condition is incident to the fourth and fifth decades of life, and men are affected twice as frequently as women Two thirds of all instances of omental torsion occur in inguinal and scrotal hernias of long duration Almost all are on the right side of the abdomen with the right lower quadrant the site of the torsion

The existence of torsion of the omentum may be attributed to adhesions, to inflammatory omental foci following subsiding acute intra-abdominal inflammatory lesions, and to a fat omentum

The peritoneal reaction usually produces a sanguineous ascites Most often there are signs of a pre-existing pedicle, and occasionally the pedicle may rupture and the mass become parasitic on the peritoneum or on a viscus Usually only a portion of the omentum in the right lower abdominal quadrant is affected, although the entire omentum may be strangulated.

The onset of symptoms is by a sudden acute, severe abdominal pain in the right lower quadrant High fever, fast pulse and increased respiration quickly ensue In some cases vomiting is intractable, in others it may be absent. On examination by the time the symptoms have become established, there is a tender abdominal tumor. The tumor, at first, is not well delineated, often owing to muscle guarding. The muscles soon become rigid Leukocytosis is present.

The diagnosis is made at the time of surgical exploration Prognosis is good when early surgical treatment is instituted.

Infarction of the Omentum. Inspection reveals necrosis and hemorrhagic extravasation into the omentum There is no suggestion as to the origin of the condition The symptoms and signs are those of the "acute abdomen" which require several days for development The condition has not been diagnosed preoperatively or prior to death The prognosis is not good despite early surgical treatment.

Solid Tumors of the Omentum. Solid tumors of the omentum are the same as those occurring in the mesentery, for the origin of the omentum is comparable with that of the rest of the mesentery

ANEURYSMS OF THE DESCENDING AORTA AND THE ABDOMINAL VESSELS

Abdominal aneurysms arise from the descending aorta (made up of the thoracic and abdominal aortas) or from main arterial branches which are extended to the principal abdominal organs; for instance the renal, the splenic, the hepatic and the iliac arteries. Moreover, dissecting aneurysms may arise in any part of the thoracic aorta and extend downward and give rise to symptoms referable to the abdomen.

Abdominal aneurysms etiologically result from (1) congenital defects in the artery, (2) syphilitic infections involving the aorta, (3) atheromatous changes in the vessels

the peritoneal cavity The swelling increases and the wall of the bowel becomes thickened until the lumen is obstructed. Ischemic necrosis often ensues.

The symptoms commence with sudden severe generalized abdominal pain, diarrhea, bloody stools and often shock The diarrhea continues until a general peritonitis is established and the abdomen becomes silent The pain usually remains generalized. Vomiting is continuous, and finally there is fecal vomiting. Neither the expulsion of vomitus nor the passage of flatus gives any relief from the distention of the abdomen or the pain.

The diagnosis is usually made at laparotomy or necropsy. Pancreatic hemorrhage, intestinal strangulation, perforated ulcer, and a twisted tumor pedicle all symptomatically resemble mesenteric thrombosis.

The disease is almost universally fatal Whether or not recovery from the occlusion ever occurs cannot be stated because of a lack of objective diagnostic data. Occasionally extensive resections of the infarcted bowel have been followed by survival of the patient

Abdominal Apoplexy (Rupture of a Mesenteric Blood Vessel). Abdominal apoplexy is a rare intra-abdominal emergency Atherosclerosis with or without aneurysmal formation is responsible for the spontaneous rupture of an artery in the abdomen. The gastric and superior mesenteric arteries usually are the ones that rupture Men are affected twice as frequently as women

In contradistinction to its counterpart, cerebral apoplexy, which may occur again and again, abdominal apoplexy rarely recurs Usually this catastrophe is fatal; an occasional patient has survived. There has never been a proved preoperative diagnosis.

ABDOMINAL EPILEPSY

Moore defined abdominal epilepsy as a disorder characterized by paroxysms of acute abdominal pain The pain is due to hypermotility of the bowel, provoked by abnormal discharges of certain neurons in the vicinity of biochemically or structurally altered cerebral tissue, presumably situated in the premotor and postmotor cerebral cortex or the diencephalon

An area of the brain just posterior to the postcentral convolution when stimulated gives pain in the abdomen like that which some patients experience before epileptic attacks Stimulation in front of this region reproduces typical epileptic seizures Patients may experience intense abdominal pain as the initial symptom of a cerebral hemorrhage Klingman reported observations on 12 children who had paroxysmal attacks of abdominal pain. The electro-encephalographic anomalies in all these were suggestive of cerebral dysrhythmia In 9 of the children neurologic symptoms consistent with convulsive disorder developed afterward Some of them remained free of symptoms under anticonvulsant therapy

In a study of 14 cases of abdominal epilepsy by Moore about half of the patients had a history of brain injury as a suggestive, and in some cases as an undoubted, relationship to the onset of abnormal cerebral discharges and the symptoms of paroxysmal abdominal pain The majority of these patients had been treated for a variety of abdominal conditions or had received treatment, equally futile, for psychoneurosis The great majority of these patients obtained relief from anticonvulsant therapy

The criteria for diagnosis are based on (1) exclusion of intrinsic visceral disease, (2) a history of attack the pattern of which is of an epileptic order and (3) objective evidence of cerebral organic disease or dysfunction

ABDOMINAL MIGRAINE

Many patients who have migraine headaches have regularly, with each headache, nausea and vomiting, and some have vomiting without headache. Still others

of the abdomen and thus may suggest the diagnosis. Roentgenologic examination may reveal calcification in the wall of the aneurysm, as an oval shadow with the periphery sharply delineated and the central portion presenting a mottled appearance.

In Long's series of 44 cases of aneurysms of the *iliac arteries*, the ages of the patients ranged from 40 years to 80 years with the greatest age incidence past 70 years. The disease was commonest in men The aneurysms which were present in the 3 women were asymptomatic. In this series the cause of aneurysm formation appeared to be arteriosclerosis in all instances In 4 of Long's cases the aneurysms produced symptoms of urinary and intestinal distress and caused the deaths of the patients by rupture with exsanguination The duration of symptoms varied from 11 days to 5 months before death In 40 cases the aneurysm was found incidentally at necropsy.

Aneurysm of the *hepatic artery* is exceedingly rare. The symptoms, when present, consist of pain in the right upper quadrant of the abdomen, jaundice, and evidence of bleeding into the alimentary tract Aneurysm of the hepatic artery is diagnosed at the time of surgical operation or more commonly at the time of postmortem examination.

Dissecting Aneurysm of the Descending Aorta. A dissecting aneurysm of the descending *thoracic aorta* produces pain in the thorax which may extend to the abdomen However, in most instances of dissecting aneurysm, when pain becomes manifest it is acute and severe and must be differentiated from that due to myocardial infarction

A dissecting aneurysm of the *abdominal aorta* begins insidiously and has a prolonged course. The illness is characterized by abdominal pain in the course of the abdominal aorta or its branches. The pain is often severe but is characterized by remissions during which there is only a dull ache present Dissecting aneurysms of the abdominal aorta may be suspected, but usually they are diagnosed at the time of necropsy unless an aortogram is made

Aneurysms may occur in the vessels of the hollow viscera, for instance the stomach or the colon They may rupture and cause severe hemorrhage, manifested by hematemesis or melena and shock The diagnosis of these lesions usually is made at the time of surgical exploration to discover and to correct the cause of the hemorrhage unless an aortogram has been made

OCCLUSIONS AND RUPTURES OF THE MESENTERIC BLOOD VESSELS

The mesenteric blood vessels may be the site of occlusion or rupture The etiology in both conditions is usually an atherosclerosis.

Mesenteric Vascular Occlusion. Mesenteric vascular occlusion occurs in aging persons.

Atherosclerosis is the most important contributing cause of mesenteric vascular occlusion. Occlusion of the mesenteric vessels sometimes follows abdominal and pelvic operations, particularly appendectomy.

Arterial occlusion results from either embolism or endarteritis Endarteritis causes a slow occlusion Men are affected more often than women

The superior mesenteric artery is most commonly occluded It is for this reason that in mesenteric occlusion the greater part of the jejunum and the ileum, and often the cecum and the ascending colon, are affected. In occlusions of the superior mesenteric artery there can be but meager development of collateral circulation, for this vessel behaves like an end artery when occluded The degree of involvement of the bowel depends on the size of the branch occluded and on the accompanying vasospasm The occlusion of either a mesenteric artery or a vein acts the same in regard to the amount of congestion of the bowel In either case congestion is the main feature The extravasation of blood which follows initiates peritoneal irritation, and free fluid accumulates in

urine rapidly ensue When the condition is severe, extreme dehydration, hypochloremia and alkalosis occur.

On examination visible gastric peristalsis is often present. Direct percussion over the stomach may initiate the peristaltic waves. A small, firm, smooth palpable tumor in the pyloric region is usually present. This tumor is best palpated when the child is asleep or while nursing before the stomach is filled Roentgenologic examination is diagnostic.

The rarer anomaly, congenital atresia of the *duodenum*, may closely simulate the symptoms of congenital stenosis of the pylorus In congenital atresia the narrowing of the bowel is in the second part of the duodenum No tumor is palpable in the epigastrium Roentgenoscopic examination reveals a complete obstruction. Duodenal atresia cannot be differentiated from congenital pyloric stenosis if the atresia is close to the pylorus The manifestations of congenital hyperplasia of the adrenal glands may closely resemble those of hypertrophic pyloric stenosis.

Hypertrophy of the Pyloric Muscle in Adults. The variation in the thickness of the pylorus in normal persons depends on the size and age of its owner. Horton admitted great difficulty in determining the actual normal size of the pylorus.

Hypertrophy and thickening of the muscle fibers of the pylorus are a very rare cause of symptoms and signs of pyloric obstruction in adults In affected adults the hypertrophy of the pyloric musculature is identical with that in hypertrophic pyloric stenosis of infancy. The condition in adults is perhaps the result of residual low-grade congenital pyloric stenosis Any other postulation is beset by the vagaries of subjective symptoms as recorded in routine history writing

Some patients have gastric symptoms and periodic attacks of vomiting which date from infancy In others there may be vague and indefinite symptoms which began, so far as the patient knows, in adult life In late or middle life some of those who are proved to have hypertrophic pyloric stenosis have symptoms, of brief duration, which resemble those of peptic ulcer and pyloric obstruction The history may be short, the symptoms progressive and the stomach achlorhydric

A positive diagnosis of hypertrophy of the pyloric muscle in adults is possible by a trained roentgenologist.

Cascade Stomach. In the cascade stomach the posterior wall of the pars cardiaca is not in the same plane with the pars media, which is anterior to its normal position, the greater portion of the vertical limb of the stomach being displaced forward The roentgenologist records that on ingestion of a small amount of barium, the barium passes and fills the pars cardiaca before it enters the pars media and the pars pylorica. Suddenly then the barium fills the pars pylorica

Cascading does not cause either subjective or objective complaints; however, like other minor congenital anomalies, it predisposes toward gastric dysfunction when the stomach is otherwise adversely affected.

Volvulus of the Stomach. The most important predisposing causes of gastric volvulus are congenital ptosis or marked relaxation of the ligamentous supports of the stomach Tears in the gastrocolic and gastrohepatic omenta permit of volvulus The spontaneous occurrence of volvulus of the stomach is aided by disorders of the diaphragm, for instance, diaphragmatic hernia, or eventration of the diaphragm, or by left phrenicectomy The intragastric causes of volvulus are hourglass stomach, gastric ulcer, malignant lesion at the cardiac end of the stomach, benign tumors of the stomach, acute dilatation of the stomach and excessive antiperistaltic movements

The symptoms are similar to those of the other acute conditions in the upper part of the abdomen A clinical preoperative diagnosis is not made

The prognosis depends on the surgical skill available and the length of time elapsed before surgical operation is performed.

Diverticula of the Stomach. Four gastric diverticula were found by Rivers, Stevens and Kirklin in 3,662 subjects of routine necropsy.

Gastric diverticula are classified as (1) true (probably congenital) and (2) false or

have nausea, vomiting and abdominal pain occurring with the headache. In a few of those who have migraine, nausea, vomiting and abdominal pain will occur without cephalalgia In this last named group the condition has been termed abdominal migraine.

THE STOMACH

The pylorus lies in the median line 1 to 2 inches (2.5 to 5.1 cm.) below the tip of the xiphoid or ensiform cartilage, when the stomach is distended, the pylorus moves 1½ to 2 inches (3 8 to 5 1 cm.) to the right. The lower border of the stomach crosses the median line 2 to 3 inches (5.1 to 7.6 cm.) above the umbilicus.

Percussion In physical diagnosis the size of the stomach may be outlined approximately by percussion, if it is filled mainly by air or gas However, if the stomach is filled mainly by liquids, as is often the case in pyloric obstruction, the outlines cannot be found by percussion

Traube's semilunar space is limited above by the edge of the left lung, indicated by the sixth interspace, externally by the spleen, indicated by the midaxillary line; and internally by the costal margin. Pleural effusion causes this space to be dull on percussion The diagnostic value of this sign has great limitations, owing to its variability

Lymphatic Structures The inferior lymph nodes of the stomach are found principally around the regions of the pylorus, and the superior gastric nodes around the lesser curvature and cardial extremity The inferior nodes drain the greater curvature toward the pylorus, while the superior nodes drain the lesser curvature and cardial end The fundus is drained by radicles which empty into the nodes which accompany the splenic artery Some nodes may be found along the greater curvature toward the pyloric end It is rare to find nodes in the middle portion of the greater curvature and quite exceptional to meet with them in the region of the fundus. In cancer of the stomach these nodes do not become palpable until late in the disease if at all.

Diseases (Anomalies) of the Stomach Due to Prenatal Influences. Absence of the stomach (agastria), doubling of the stomach and accessory stomach have been recorded There are congenitally small and congenitally large stomachs The greatly enlarged stomach is often accounted for by the presence of hypertrophic pyloric stenosis or duodenal atresia Actual developmental megalogastria probably occurs

A congenitally right-sided stomach is present with general transposition of viscera A failure of normal rotation of the foregut accounts for the presence of the stomach above the liver on the right side. This anomaly is compatible with normal digestion and health The situation of the stomach when associated with eventration of the diaphragm may resemble hydropneumothorax. Complete inversion of the stomach characterized by the orad position of the greater curvature together with a left lateral position of the cardia is rare In such a stomach the duodenal cap is directed downward and the transverse colon often angulates in its midportion.

Congenital Hypertrophic Pyloric Stenosis. Congenital hypertrophic pyloric stenosis is occasionally observed in otherwise healthy infants. The sex ratio is approximately 4 boys to 1 girl Several members of the same family may have the anomaly.

There is hypertrophy of the pyloric musculature. In many instances the degree of organic constriction of the pyloric lumen is insufficient to cause complete obstruction and there is an additional element of spasm. The thickening of the pyloric musculature accounts for the oval, firm tumor The gastric wall in the prepyloric region may be thickened and some dilatation of the stomach may be present. Simple hypertrophy of the pyloric muscle in the adult is most likely the result of this congenital anomaly.

The symptoms usually commence during the second week after birth but may be delayed to a later age There is regurgitation which progressively increases until supplanted by periodic spells of vomiting The child does not vomit after each feeding, but after several feedings have accumulated, and will promptly resume nursing immediately after the vomiting In the severely obstructed pylorus the vomitus is free from bile Loss of weight, constipation, and decrease in the quantity of

have revealed streptococci and, in some cases, staphylococci, colon bacilli and pneumococci There is diffuse suppurative infiltration of the submucosa with thickening of the walls A localized abscess may rupture into the stomach or into the peritoneum.

The important symptoms are pain, high fever, vomiting, dry tongue and dehydration and occasionally jaundice The vomitus contains pus. Occasionally there is a tumor which can be palpated.

The prognosis is grave The diagnosis rarely is made before death because the patient is too ill to be examined roentgenologically or endoscopically.

Acute Gastritis of Toxic Origin (Exogenous Gastritis) This disease is initiated by swallowing of chemical, thermal, mechanical or bacterial irritants. Common examples of these irritants are alcoholic beverages and medicines, such as salicylates, ammonium chloride, quinine, creosote, coal-tar products, iodides and bromides, administered either in large doses or to hypersensitive subjects. Mechanical distention brought about by eating too much, rarely, if ever, causes an inflammatory reaction in a stomach. A combination of alcoholic drinks and gluttony, however,

Endoscopic examinations are not permissible during or immediately following an episode of acute exogenous gastritis Observations of the interior of the stomach through fistulas of living persons do not contribute much to the understanding of this form of gastritis A fistulous stomach is not normal

Epigastric burning and distress of varying intensity, nausea, salivation, anorexia, vomiting, diarrhea, and disagreeable taste in the mouth are the common symptoms. In the more severe disorders, particularly if associated with diarrhea, there may be present extreme prostration, weakness and intractable nausea and vomiting. The vomitus contains much mucus If vomiting is protracted, the vomitus eventually consists of bile Hydrochloric acid may or may not be present in the gastric contents. A temporary suppression of acid secretion may occur during the acute phases of the disorder.

The general examination is informative mainly because of the negative evidences of systemic disease or other abdominal disease.

Acute (exogenous) gastritis may be suspected of being the cause of the forementioned symptoms if accompanied by a history of ingestion of a causative agent. Reflex symptoms resulting from trauma, migraine and acute abdominal diseases are always considered

Acute Corrosive Gastritis Corrosive gastritis results from the swallowing of organic acids (carbolic) or mineral acids or alkalies, or such poisons as phosphorus, bichloride of mercury or insecticides, ammonia, arsenic, and comparable substances. The most frequent causes of corrosive gastritis are lye, bichloride of mercury, carbolic acid and lysol (see Chapter 19)

With the noncorrosive poisons the pathologic process in the stomach consists of acute degeneration of the glandular elements and hemorrhage. With strong poisons the mucous membrane is destroyed extensively and may be converted into a brownish black eschar. In less severe grades of toxic gastritis, there may be regions of necrosis surrounded by inflamed tissue, and the submucosa is hemorrhagic and infiltrated

The first symptoms are feelings of strangulation, intense burning pain in the mouth, throat and stomach, salivation, great difficulty in swallowing, and constant vomiting which follows immediately. The vomitus is bloody and sometimes contains portions of the mucous membrane

The primary immediate concern in most of these cases is with the symptoms of the systemic poison and the administration of the appropriate antidote (see Chapter 19).

If a mild corrosive poison has been swallowed, the examination does not reveal significant findings; if a strong corrosive substance has been ingested, there will be

acquired. The occasional occurrence of concomitant diverticula in the duodenum and in the colon is further evidence that the true diverticula are due to prenatal influences The pouches frequently are situated in the posterior wall near the lesser curvature distal to the entrance of the esophagus. They may occur in other parts of the stomach including the pylorus True diverticula of the stomach may contain ectopic (pancreatic) tissue

Acquired diverticula are subdivided into the pulsion and traction varieties. The origin of these is ascribed to such vagaries as increased intragastric pressure, adhesions, and what not

Gastric diverticula are single and rarely exceed ⅘ inch (2 cm) in diameter. Retention in the pouch may occur when the stoma of the pouch is small.

Gastric diverticula are found accidentally by the roentgenologist in patients of any age Generally they are asymptomatic The symptoms if present are usually best accounted for by independent accompanying lesions of the esophagus, stomach, duodenum, or gallbladder Asymptomatic massive hemorrhage has been recorded, but unfortunately for the hypothesis for diverticular hemorrhage, these patients also have had peptic ulcer of the duodenum. If hemorrhage does occur it probably arises from ectopic tissue in the diverticulum The diagnosis is established by roentgenologic examination

Diseases of the Stomach Due to Bacteria and Those Due to Corrosives and Intoxication. Infections of the stomach exist in both acute and chronic forms. An acute or chronic gastritis may be caused by infection by lower plant and animal parasites or may be due to the effects of trauma from the poisonous corrosive effects of many and varied substances Often a gastritis arises from unknown causes.

Acute Gastritis. *Acute Infectious Gastritis* The stomach is peculiarly refractory to the direct invasion of bacteria unless the mucous membrane has been injured Infectious gastritis has been described in association with acute systemic diseases such as diphtheria, scarlet fever, pneumonia and other infections In these infections the lower organisms are carried through the blood stream to the stomach, where either the bacteria or their toxins are spread to the walls of the stomach.

SYMPTOMS The symptoms, if there is fever, are similar to the initial symptoms of many infectious diseases If an intense headache and delirium are present, the illness may resemble meningitis, or if the abdominal pains are intense, the attack may resemble gallstone colic or appendicitis

In the mild acute form of gastritis there are anorexia, vomiting, and dyspeptic symptoms which frequently accompany any acute febrile illness. In the course of the attack the temperature reaches 102 to 103 F (38 8 to 39 4 C) The average duration of the attack is 1 day, but it may last 3 days and occasionally longer. There is usually constipation; however, diarrhea may be present In severe gastritis of sudden onset, with chill and fever, the symptoms are like those of a severe infection. During the course of such systemic diseases as diphtheria, scarlet fever, and pneumonia there may develop an acute gastritis

On examination the tongue shows the effects of dehydration, a finding never missed by physicians of former times. Herpes may appear on the lips The abdomen may be somewhat distended and tender in the epigastric region

At first the substances ejected from the stomach contain food; later, bile-stained fluid and much mucus Examination of the vomitus reveals, as a rule, absence of hydrochloric acid and presence of lactic and fatty acids Leukocytosis (up to 15,000 leukocytes per cubic millimeter of blood) may be present.

The diagnosis is inferred if the illness clears within a few days If the symptoms do not clear, a gastroscopic examination will result in a correct diagnosis. The finding, however, of an acutely inflamed mucosa of the stomach may not mean that the patient has acute gastritis only There may be an acute systemic infection also

Acute Suppurative or Purulent Gastritis Acute suppurative gastritis may be a complication of either bacteremia or ulcer of the stomach. Young men are affected more frequently than women. Microscopic examinations of extirpated gastric tissue

om postoperative complications due to any type of general anesthesia Achlorydria, avitaminosis (vitamins B and C), allergic disorders, *Giardia lamblia*, and ichobezoars and phytobezoars are likewise suggested as causes for chronic gastritis

Ulcerative Gastritis. Severe ulcerative gastritis is a rare complication of chronic uodenal ulcer but when present may become constantly accompanied by symptoms. : is one cause of an inability to control peptic ulcer by medical treatment

Postoperative Gastritis Severe gastritis in the stomach that has been operated n is usually irreparable unless the gastroenterostomic passage is discontinued However, the prognosis for patients who have mild postoperative gastritis is decidedly iore hopeful than it is for those who have severe hypertrophic or atrophic forms f the disease

Up to this point the various forms of gastritis which have been considered have ome sort of an etiologic assignment. The possible causes of chronic gastritis have een enumerated Before proceeding, it is necessary to amalgamate these possible rigins and simply to state that they may cause either hypertrophic, atrophic, or form of mixed chronic gastritis; any one or all may arise from the etiologic agents vhich have been enumerated. In other words, the individual reaction to a stimulus annot be forecast

Hypertrophic Gastritis Hypertrophic gastritis is characterized by the tendency oward thickening of the mucosa and other layers of the gastric tissues, especially oward the pyloric segment, in which the changes may be limited

The sex incidence corresponds to that of duodenal ulcer, which is commoner n men than in women Hypertrophic gastritis may occur at any age.

Pollard and Cooper selected 50 patients who had hypertrophic gastritis who vere entirely free of any other evidence of organic disease, to determine whether or not they presented any consistent clinical symptoms as a result of their disease. The features which were commonly present and which should serve as a diagnostic aid were a burning sensation or discomfort in the epigastrium before, immediately after, or in about 2 hours after eating The discomfort was at times relieved by food or sodium bicarbonate Free acid in the gastric contents in normal or increased amounts was common However, generally the symptoms of this condition which can be assigned to pathologic findings occur in association with other diseases or with a condition produced by the gastritis which is similar to another disease, for nstance peptic ulcer

The time and situation of the pain may be those of a peptic ulcer, but the relief of pain by ingestion of food and antacids is often lacking The slightest dietary indiscretion provokes an exacerbation of symptoms Usually the appetite is not decreased, but loss of weight is definite because of dieting and sitophobia With the exception of hemorrhage, complications are comparatively rare Hemorrhage may be decidedly a prominent symptom in hypertrophic gastritis Intestinal symptoms, abdominal cramping and diarrhea are rare

Hypertrophic gastritis and peptic ulcer may be associated, a state which is revealed by gastroscopic examination The roentgenologic examination will reveal no definite diagnostic evidence of the disease When the symptoms of duodenal ulcer progress to the stage at which there is no remission of the suffering, the presence of hypertrophic gastritis is one of the complications which can create such a predicament

Hypertrophic gastritis after gastroenterostomy is not a frequent cause of the symptoms following anastomotic operations The symptoms of postoperative gastritis cannot be distinguished from those of peptic ulcer. They may be temporarily relieved by bland food or alkalies, but usually such relief is short-lived

In postoperative gastritis the questions always arise as to whether the patient had the gastritis before the operation and whether the gastritis failed to heal after the operation. The chances are that the gastritis existed prior to the operation.

evidence of the poison on the lips and in the mouth unless the poison was sipped through a quill or straw The patient often presents evidences of both physical and mental agony The abdomen is tender, distended and painful on pressure. The signs of shock or collapse and, sometimes, convulsions may be present. If the patient is examined a day or two after the ingestion of the poison, there may be petechiae in the skin and blood in the urine When the poisoning is less intense, there are sloughs in the mouth and gullet which may separate, leaving infected ulcers which may heal or which may lead to death from perforation, infection or exhaustion

The diagnosis of toxic gastritis usually is easy, as inspection of the mouth and pharynx reveals, in many instances, corrosive effects An examination of the vomitus may indicate the nature of the poison

Chronic Gastritis. *The term chronic* gastritis has become established despite strong argument against it The terms hyperacid gastritis and anacid gastritis are used to designate whether the gastritis is accompanied by hyperacidity or by anacidity. Pyloric gastritis, antral gastritis, fundic gastritis and pangastritis are used to indicate the situation of the more obvious changes as detected by gastroscopic or roentgenologic study.

Gastric function in all types of gastritis is so irregular and equivocal that it cannot be the basis of classification Schindler h [illegible] convincing proof of the frequency and significance of [illegible] to superficial, atrophic and hypertrophic varieties [illegible] chronic gastritis has been established by a method of taking biopsies from the gastric wall without ligatures or clamps If a normal mucosa is found gastroscopically, a normal histologic appearance of the biopsic tissue is expected

In this discussion of gastritis etiologic factors will be emphasized when known or suspected

The etiologies of chronic infectious gastritis in adult life may depend on an initial damage to the gastric mucosa resulting from acute infectious diseases contracted in childhood Many acute infectious diseases (due to bacteria, viruses or fungi) may damage the mucosa of the stomach to a degree which will permanently impair its secretory function and thus originate a chronic gastritis

In chronic infectious gastritis the symptoms are vague and indefinite. The findings on physical examination as well as the roentgenologic examination are characterized by an absence of positive evidence The diagnosis is established by endoscopic examination.

Chronic Irritative Gastritis Chronic gastritis may arise from the ingestion of gastric irritants For instance, injury to the gastric mucosa may follow an acute irritative gastritis initiated by concentrated alcohol or other corrosive agents or by food poisoning

Gray and Schindler concluded, after examining 100 men who had consumed an average of 2.8 pints of alcohol daily for more than 20 years, that the stomachs of 55 per cent were essentially normal In 45 per cent who had gastric disease it consisted mainly of superficial gastritis, atrophic gastritis or a combination of the two

No correlation was observed between the incidence and severity of the gastritis and the duration of the alcoholism, the amount of alcohol drunk, the use of nicotine, dental infection or vitamin deficiency. Why the drinking of alcohol is accompanied by severe and extensive gastritis in some cases and not in others is difficult to understand.

A long list of suspected substances which have had their protagonists as the cause for chronic gastritis may be enumerated, such as infected saliva, tobacco (chewed, dipped or smoked), drugs and condiments (particularly pepper) It is known that in heart failure and uremia there may be a stasis of blood in the gastric wall which may eventuate in gastritis Some gastritis almost always accompanies pyloric and duodenal obstruction. Gastritis may follow gastroenterostomy or result

membrane is grayish green This same mucosal appearance has been described in cases of pernicious anemia

Roentgenologic examination is essential to the diagnosis of gastritis in the same way that a general physical examination is essential Its value is in ruling out circumscribed lesions, particularly peptic ulcer, carcinoma and hiatus hernia.

All gradations in gastric acidity determined by analysis of gastric contents may be found in conjunction with all types of chronic gastritis. In diagnosis the determination of acidity has no value, in therapeusis the determination of gastric acids is helpful If there is a definite trend in values for gastric acid in cases of chronic gastritis, that trend is downward

Diagnosis of Chronic Gastritis. A clinical diagnosis of chronic gastritis is made only by exclusion The diagnosis, however, depends on the gastroscopic findings There is danger of attaching too much significance to minor aberrations from the normal mucosal image as viewed by the gastroscope

The most serious complication of hypertrophic gastritis is development of pyloric obstruction or severe hemorrhage from erosions and ulcerations In severe hypertrophic gastritis the lesions never heal completely even though the patients may become symptom free Carcinomatous change is not to be anticipated in hypertrophic gastritis, nor does hypertrophic gastritis eventuate in atrophy of the gastric mucosa.

Those who have atrophic gastritis are prone to development of severe hypochromic anemia, pernicious anemia or gastric malignant lesions

Epidemic Nausea. Epidemics of nausea have been recorded from time to time It seems that the maximal epidemic curve occurs in the autumn of the year. The incubation period appears to be less than one week The disturbance sets in suddenly with violent nausea and vomiting together with dizziness resembling motion sickness, and is over in a day or two There is no abdominal pain or diarrhea. The cause is unknown but a viral etiology has been suspected

Tuberculosis of the Stomach. Tuberculosis of the stomach is rare. The disease occurs oftener in men than in women Primary invasion of the stomach accompanies pulmonary tuberculosis and acid-fast lesions in the abdomen or the pelvis, or in the bones, epididymides, kidneys or other parts of the body In rare instances the tubercle bacilli may directly invade the gastric mucosa by entrance into a nonspecific lesion in the stomach such as a malignant tumor or a peptic ulcer.

Broders described the various pathologic manifestations of gastric tuberculosis They include single or multiple ulcers, miliary tubercles in association with a generalized miliary tuberculosis, solitary tubercles, pyloric stenosis, tuberculous nodules, and tuberculous lymphangitis The ulcerating gastric lesions are the commonest The ulcers are either single or multiple They seldom penetrate the muscular layer. Pyloric stenosis is secondary to either a tuberculous ulcer or a granuloma

Often the symptoms of tuberculosis of the stomach are obscured by the other symptoms of the disease In many cases gastric symptoms may be absent There may be peptic ulcer-like epigastric distress, and vomiting of a sufficient severity to suggest pyloric obstruction The loss of weight and strength is constant and severe When gastric tuberculosis is advanced, hemorrhages from the stomach often occur

On examination, palpation often reveals a gastric mass, but more frequently roentgenologic examination reveals signs of organic gastric disease. Clinical evidence of tuberculosis elsewhere in the body is usually present In most instances advanced tuberculosis of the lungs or of the intestinal tract is present.

The diagnosis of gastric tuberculosis cannot be made without confirmation by histologic study. The presence of tuberculosis in the lungs or elsewhere in the body, particularly if the disease is in an advanced stage, may suggest the possibility of gastric involvement with tuberculosis.

Hypertrophic gastritis and cancer do not have a cause-and-effect relationship When an aged patient gives a short history of epigastric distress after dietary indiscretions or after indulgence in alcoholic beverages, with or without having had an acute illness or hypertrophic gastritis, it is suggestive of cancer and not an exacerbation of a gastritis This history is more suggestive of cancer if there are nausea after meals, anorexia and regurgitation and vomiting. In these cases anemia may be present, often of a hypochromic iron deficiency type.

The diagnosis of hypertrophic gastritis which simulates cancer of the stomach is established by exclusion of cancer of the stomach by roentgenologic examination and endoscopic recognition of the gastritis

Atrophic Gastritis. Atrophic gastritis is characterized by a thinning of the mucous membrane and often of the rest of the coats of the stomach

Since this disease affects patients of middle life and later, at least one or more of the etiologic factors enumerated as possible causes of chronic gastritis have had time to act, and since no one can live a model life and never indulge in at least a cup of hot tea, a highball, or in pepper sauce on turnip greens, one or more of the irritants will have been ingested by the patient. An "etiologic agent" can always be found

The digestive symptoms in atrophic gastritis are of variable duration and usually of periodic occurrence The common complaint is a postprandial, localized, dull epigastric discomfort accompanied by anorexia and nausea. Night pain is not present and relief does not follow the ingestion of food and antacids. Vomiting and bleeding are rare General symptoms are perhaps the most definite There are recurrent episodes of extreme fatigue and weakness; these patients are sad, depressed, and often have been lifelong dyspeptics and in the habit of condemning themselves for having eaten or drunk the wrong things

EXAMINATION IN CHRONIC GASTRITIS. The physical examination of a patient who is suspected of having chronic gastritis is performed in order to eliminate some other abdominal or constitutional disorder capable of causing the complaints. If tenderness is present in the epigastrium or in the upper part of the abdomen, it is widespread and not extreme

In some there is present sore tongue or sore mouth Some patients experience numbness or tingling in the hands and feet In many cases the blood is normal or, on microscopic examination, may be slightly hypochromic The gastric secretory findings may include achlorhydria or a normal acidity

If the gastroscopist reports an acute or a catarrhal gastritis involving only the uppermost layers of the gastric mucosa, this finding should not be considered diagnostically conclusive, particularly if the process consists of only small areas of erosion attended with a minimal amount of adjacent inflammatory reaction This type of gastritis is evanescent and tends to disappear rapidly However, in some instances it may progress to the hypertrophic state or the mixed state

If the gastroscopist reports gastritis, the mucosa presenting a simple swelling and congestion of the gastric folds, which have lost their normal smooth glistening appearance, or some thickening of the gastric mucosa and the presence of mucopurulent secretion between the folds, the condition is usually hypertrophic gastritis If the condition should be more severe, mention will be made that the mucosa assumes a nodular or cobblestone appearance. If the disease is advanced, a distinct hypertrophy of the gastric rugae, patches of ulceration and surrounding edema, infiltration, and a loss in the normal elasticity of the gastric wall will be described This latter type of gastritis is recognized by the roentgenologist

Atrophic gastritis occurs less frequently than other forms of gastritis and is reported as being characterized by extreme thinning of the gastric mucosa The gastric rugae disappear and the submucosal vessels come into view. The mucous

swelling, necrosis, and erosion. Pyloric obstruction may enhance a mycotic infection

The symptoms in either mode of infection by any kind of fungi may simulate those of acute or chronic gastritis, ulcer, or malignant disease of the stomach.

The diagnosis is based on the laboratory findings and on biopsy performed at the time of surgical operation Heavy mold flora, revealed by examination of the vomitus or of the gastric contents, may suggest the diagnosis Fungi present in achlorhydric gastric contents have little or no significance.

The prognosis is guarded in cases of proved blastomycotic or actinomycotic invasion. The patients who have other mycotic infections seem to fare better.

Diseases of the Stomach Due to Foreign Bodies in the Stomach. Foreign bodies present in the stomach may be small bodies accidentally or intentionally swallowed, bezoars, and endogenous bodies such as gallstones.

Swallowed Foreign Bodies. The smaller solid objects accidentally or intentionally swallowed, such as seeds, fruit stones, pebbles, coins, marbles, buttons, pieces of bones, and finger rings, usually emerge from the anus without causing injury A sharp object such as a fish bone, an open safety pin, or a needle may pass on to the stomach or intestine and produce abrasions of the mucous membrane or penetrate more deeply to cause bleeding and later abscess formation, and occasionally granuloma. Actual perforation is rare, but walling off of the perforated object and the resulting formation of an abscess or a foreign body granuloma is relatively common A needle may migrate to distant parts, for instance, to the heart

Obstruction of the normal pylorus as the result of a swallowed foreign body may occur, but more often the obstructed pylorus is abnormally small Obstruction in the intestine, if such occurs, takes place most frequently in the lower part of the ileum or in the descending colon

If the patient has mental disease, the presence of gastric symptoms and of a palpable abdominal tumor requires consideration, in differential diagnosis, of the possibility that he has swallowed a foreign body The ingestion of pieces of soluble heavy metals rarely causes metallic poisoning In the mentally normal patient the history of swallowing a foreign body is obtained

Before the diagnosis of swallowing of an object is made, the examiner should try to be sure that a missing article has been swallowed, not lost Attempt at removal of the object, when first seen roentgenoscopically, requires judgment and experience There is no emergency great enough to justify the attempt at removal by an unqualified operator, for use of the gastroscope by unskilled hands may prove disastrous It is wise to watch and wait if the swallowed object is small and not sharp Frequent roentgenoscopic re-examinations will often reveal the satisfactory passage of the object through the alimentary canal If the swallowed body remains in the stomach, the decision concerning the type of treatment to be employed is made by the endoscopist, whose services should be obtained as soon as the emergency arises

The large objects swallowed by the performer at the circus and by the insane usually find their way out of the alimentary canal through the anus Large objects, however, such as spoons, knives or forks may cause traumatic ulceration, perforation, or obstruction in some part of the alimentary tube.

The Bezoars. The bezoar is a concretion in the stomach It may be composed of hair (trichobezoar), vegetable or plant fibers (phytobezoar), a combination of hair and vegetable fibers (trichophytobezoar), or mineral medicaments or any other insoluble substance of physical and chemical constitution which can withstand the action of the gastric juice and the emptying efforts made by the stomach

Trichobezoar or hairball is the type of bezoar most frequently observed in man. Hair swallowing is confined principally to nervous children and mentally deranged women A trichobezoar may fill the stomach, making a complete cast of the organ.

Syphilis of the Stomach. Gastric manifestations during the primary stage of syphilis are rare In more advanced syphilis, however, there may be present mild gastric dyspeptic symptoms such as anorexia, nausea and epigastric discomfort. These symptoms represent the local gastric response to a systemic infection.

Congenital syphilis of the stomach is not encountered in clinical practice of medicine. Acquired syphilis of the stomach is commoner in men than in women and occurs 10 to 15 years earlier than does carcinoma of the stomach

It is difficult to estimate the incidence of gastric syphilis O'Leary has recorded a clinical diagnosis of gastric syphilis a number of times. Many of O'Leary's patients were examined by Eusterman, who concurred in the diagnosis.

Many pathologists have studied the stomachs of syphilitic patients but have never made a diagnosis of gastric syphilis on histologic findings alone However, it seems that syphilis of the stomach can be manifested by (1) a single lesion, or multiple lesions, taking the form of a nodular ulcerative syphilid, (2) diffuse nodular infiltration or chronic fibrosis and (3) in some cases, multiple serpiginous ulcers

Eusterman found it impossible to formulate a definite symptomatology For the purpose of clinical analysis only, he divided cases of gastric syphilis into three groups, which in the following enumeration are described in order of frequency of occurrence. (1) Those in which the onset of symptoms of epigastric distress or pain occurs immediately after meals and there is a quantitative type of dyspepsia The symptoms become progressively worse and the patients eventually require frequent feedings—evidence of a reduced gastric capacity Vomiting and pain are definite, but nausea and anorexia are much less evident than in gastric carcinoma The patients are often in a state of partial or advanced starvation. (2) Those termed the ulcer type because of the "pain-food-ease" sequence The symptoms are not so definite as those that occur in duodenal ulcer (3) Those, the smallest group, in which symptoms begin with mild gastric discomfort, often occurring about one-half hour after meals Ingestion of food or alkali fails to give relief The discomfort increases and there is a tendency for the distress to appear earlier after meals. Gradually there is a loss of strength and weight.

The general examination may reveal evidence of pre-existing or present active syphilitic lesions

The diagnosis of gastric syphilis often is impossible Existence of the disease may be suspected, however, and at times the diagnosis is made if there are the following findings· (1) untreated tertiary syphilis, (2) defect in the stomach apparent on roentgenologic examination, (3) failure to relieve the symptoms by usual treatment for ulcer and (4) symptomatic relief with disappearance of the roentgenologic defect after appropriate antisyphilitic treatment

It is not often wise to try to prove a diagnosis as outlined In many cases the evidence strongly favors the diagnosis of carcinoma of the stomach In these cases surgical exploration should be advised.

The term catarrhal luetic gastritis when used, indicates gastritis and achlorhydria in a case of proved syphilis

Mycotic Infections (Including Actinomycosis) of the Stomach. Local circulatory disturbances in the gastric mucosa may predispose toward fungous disease of the stomach. A diphtheria-like membrane may be formed at first, to be followed by ulceration. The ulcers may be single or multiple, small or large. They rarely penetrate or perforate. The necrotic tissue from such lesions is infected with the mold The sulfur bodies of the ray fungus may be discovered in an actinomycotic ulcer.

During the course of an infection by any one of the higher plant organisms, and particularly in blastomycosis, the stomach may be infected by a *blood-borne infection* In a stomach affected by a blood-borne infection the capillaries of the gastric wall are obstructed by the organisms, with resultant hemorrhagic gastric

tion resulting from adhesions or constriction at the site of the sutured perforation. In rare instances hourglass deformities are associated with gastrojejunal ulceration, partial resection of the stomach and gastrostomy. In an occasional instance the deformity seems to be idiopathic in origin

In hourglass contraction due to gastric ulcer the communication between the upper and lower segments is situated near the lesser curvature, whereas in syphilis and cancer the communication often is in the middle of the stomach. Pyloric stenosis is found in 1 of every 4 stomachs which have hourglass deformities.

The patient often complains of having had recurring attacks of epigastric distress occurring after meals. The symptoms observed are those of gastric or duodenal ulcer. On palpation there may be epigastric tenderness In thin patients peristalsis may be visible

The clinical recognition of hourglass stomach is not possible The roentgenologic examination may reveal more than one contraction producing deformities Trilocular and multilocular stomachs may be described by the roentgenologist, and these have the same etiology and significance as the common hourglass deformity.

Tumors of the Stomach. New growths of the stomach comprise both benign and malignant tumors

Benign Tumors. In the experience of Eusterman only 1.3 per cent of all gastric tumors proved by operation were benign

The incidence of benign gastric tumors does not differ in the two sexes.

Benign gastric tumors are composed of epithelial, connective, vascular, nervous, fatty, or mixed tissues, or arise in association with these tissues Eusterman recorded distribution in order of the frequency of occurrence as follows (1) epithelial origin, adenomatous polyps, adenomas (benign cystic polyp), polyposis, and papillomas and (2) connective tissue origin leiomyomas, fibromyomas, adenomyomas, myxofibromas, hemangiomas, fibromas, neurofibromas, lipomas and dermoid cysts

SYMPTOMS The symptoms of benign tumors of the stomach depend on the size, location, and extension of the growths and on whether ulceration, bleeding, or malignant change is present The small tumors situated away from the sphincters, and even the large tumors in the fundus, do not cause subjective symptoms until they become large enough to be manifested on account of size A benign neoplasm situated near the esophageal orifice causes dysphagia When situated near the pylorus, there may be manifestations of obstruction of the pylorus

The duration of the symptoms attributed to benign gastric tumors varies between 6 and 18 months Massive hemorrhage into the stomach is the most constantly present symptom This is particularly true of leiomyoma, adenoma and neurogenic tumors There is a continuous loss of blood between severe hemorrhages or independently of them Anemia frequently is severe The association of gastric polyp with pernicious anemia and gastroscopic evidence of atrophic gastritis and carcinoma of the stomach occurs frequently enough to be considered a significant relationship

The prolapsing of a polyp through the pylorus may cause sudden acute severe [illegible] e stom- [illegible] polyps [illegible] pyloric obstruction

Benign tumors of the stomach may be multiple as in gastric polyposis A gastric polyposis may be present and symptomless if bleeding has not occurred. When there are symptoms, they are not distinctive If bleeding has occurred, there are often weakness and pallor These tumors are potentially malignant, but they may permit of reasonable health for a number of years

In the absence of pyloric obstruction or severe anemia the physical examination is important because of the negative findings. Palpable benign lesions of the stomach are rare, although large tumors may be palpated If an anemia is present,

The *phytobezoar* is composed primarily of vegetable matter from the ingestion of certain foods Enmeshed in its substance there are also food materials of other types and epithelial detritus Some of the causative ingredients that have been observed in phytobezoars are celery, the skins and seeds of prunes, plums and muscadines, and cotton. In about three fourths of all cases, however, the chief offender is the fruit of the wild persimmon Persimmons contain a considerable amount of pectin and a high percentage of the soluble "shibouî" gum, which is an effective mordant in the formation of phytobezoars.

Trichophytobezoars are composed of both hair and vegetable matter. Formation of the foreign body may follow the drinking of furniture polish, which is an alcoholic solution of shellac and resins The shellac and resins are precipitated in the stomach after the drinking of water

Various medicaments have been retained in the stomach as foreign bodies

The offending substance or substances may be eaten on one occasion or on several occasions without immediate symptoms Months or even years may elapse before manifestations appear The symptoms present depend on the size of the bezoar Frequently the symptoms comprise a sense of dragging, fullness, lump or heaviness in the epigastrium, cramplike epigastric pain and periodic attacks of vomiting. As time passes, gastritis develops as a result of the foreign body, and the symptoms are those of gastritis As the bezoar increases in size, symptoms of pyloric obstruction appear Peptic ulcer may develop concomitantly with the bezoar, and with its advent the characteristic symptoms of peptic ulcer disease are present An epigastric tumor may be palpated

The roentgenologic diagnosis of bezoar usually is definite. When there is a history of the swallowing of hair or persimmons or other significant material, and there is present a freely movable, palpable tumor in the epigastrium, the tentative diagnosis of bezoar is justified

Endogenous Foreign Bodies. Gallstones occasionally gain entrance into the stomach through a fistula, cholecystogastric or cholecystoduodenal The stone may be vomited, but usually it passes into the intestine and if it proceeds beyond the lower part of the ileum, will be expelled through the rectum

In some cases foreign bodies enter the stomach as a result of violence

A foreign body which would pass through the normal pylorus may be retained in the stomach as a result of pyloric stenosis In the stomach of a patient who has pyloric stenosis the surgeon may find seeds, fruit skins and masses of food detritus which cannot pass out. In some instances antacid tablets of magnesium carbonate, calcium carbonate and similar drugs may be found by the surgeon or revealed by roentgenoscopic examination

Diseases of the Stomach Due to or Consisting of Static Mechanical Abnormality. *Prolapse of the Gastric Mucosa Through the Pylorus.* Prolapse of the gastric mucosa through the pylorus is a rare cause of gastric symptoms

Moderate redundancy of the pyloric mucosa is common, and is without symptoms When the prolapsing mass is large, there are gastric retention and partial pyloric obstruction When complete prolapse into the duodenum occurs, the differentiation between pedunculated tumor and prolapsing gastric mucosa will often be impossible before surgical operation is performed If roentgenologic examination reveals a large defect in the pyloric canal and a negative shadow in the duodenal bulb, the condition may be diagnosed correctly by the roentgenologist However, often it may be impossible to distinguish it from pyloric ulcer, hypertrophic gastritis, or carcinoma

Organic Hourglass Deformity of the Stomach. In an hourglass deformity of the stomach the viscus is divided into two cavities connected by a channel This contraction occurs more frequently in women than in men The usual cause is a healed peptic ulcer which was or is situated in the middle segment of the stomach. However, an hourglass deformity of the stomach may develop after a free perfora-

tion resulting from adhesions or constriction at the site of the sutured perforation. In rare instances hourglass deformities are associated with gastrojejunal ulceration, partial resection of the stomach and gastrostomy. In an occasional instance the deformity seems to be idiopathic in origin.

In hourglass contraction due to gastric ulcer the communication between the upper and lower segments is situated near the lesser curvature, whereas in syphilis and cancer the communication often is in the middle of the stomach Pyloric stenosis is found in 1 of every 4 stomachs which have hourglass deformities

The patient often complains of having had recurring attacks of epigastric distress occurring after meals The symptoms observed are those of gastric or duodenal ulcer *On palpation there may be epigastric tenderness. In thin patients peristalsis* may be visible

The clinical recognition of hourglass stomach is not possible. The roentgenologic examination may reveal more than one contraction producing deformities Trilocular and multilocular stomachs may be described by the roentgenologist, and these have the same etiology and significance as the common hourglass deformity.

Tumors of the Stomach. New growths of the stomach comprise both benign and malignant tumors

Benign Tumors. In the experience of Eusterman only 1.3 per cent of all gastric tumors proved by operation were benign

The incidence of benign gastric tumors does not differ in the two sexes.

Benign gastric tumors are composed of epithelial, connective, vascular, nervous, fatty, or mixed tissues, or arise in association with these tissues. Eusterman recorded distribution in order of the frequency of occurrence as follows (1) epithelial origin· adenomatous polyps, adenomas (benign cystic polyp), polyposis, and papillomas and (2) connective tissue origin leiomyomas, fibromyomas, adenomyomas, myxofibromas, hemangiomas, fibromas, neurofibromas, lipomas and dermoid cysts

SYMPTOMS. The symptoms of benign tumors of the stomach depend on the size, location, and extension of the growths and on whether ulceration, bleeding, or malignant change is present The small tumors situated away from the sphincters, and even the large tumors in the fundus, do not cause subjective symptoms until they become large enough to be manifested on account of size A benign neoplasm situated near the esophageal orifice causes dysphagia. When situated near the pylorus, there may be manifestations of obstruction of the pylorus

The duration of the symptoms attributed to benign gastric tumors varies between 6 and 18 months. Massive hemorrhage into the stomach is the most constantly present symptom This is particularly true of leiomyoma, adenoma and neurogenic tumors There is a continuous loss of blood between severe hemorrhages or independently of them Anemia frequently is severe The association of gastric polyp with pernicious anemia and gastroscopic evidence of atrophic gastritis and carcinoma of the stomach occurs frequently enough to be considered a significant relationship

The prolapsing of a polyp through the pylorus may cause sudden acute severe symptoms of pyloric obstruction Retraction of the prolapsed polyp into the stomach usually occurs and is followed by symptomatic relief Prolapsing pyloric polyps often bleed so that anemia may accompany the syndrome of intermittent pyloric obstruction

Benign tumors of the stomach may be multiple as in gastric polyposis A gastric polyposis may be present and symptomless if bleeding has not occurred When there are symptoms, they are not distinctive. If bleeding has occurred, there are often weakness and pallor. These tumors are potentially malignant, but they may permit of reasonable health for a number of years

In the absence of pyloric obstruction or severe anemia the physical examination is important because of the negative findings Palpable benign lesions of the stomach are rare, although large tumors may be palpated If an anemia is present,

The *phytobezoar* is composed primarily of vegetable matter from the ingestion of certain foods. Enmeshed in its substance there are also food *materials of other types* [illegible] Some of the causative ingredients that have been observed in [illegible] and muscadines, and cotton. [illegible] the fruit of the wild persimmon. Persimmons contain a [illegible] and a high percentage of the soluble "shiboul" gum, which is an effective mordant in the formation of phytobezoars.

Trichophytobezoars are composed of both hair and vegetable matter. Formation of the foreign body may follow the drinking of furniture polish, which is an alcoholic solution of shellac and resins. The shellac and resins are precipitated in the stomach after the drinking of water.

Various medicaments have been retained in the stomach as foreign bodies.

The offending substance or substances may be eaten on one occasion or on several occasions without immediate symptoms. Months or even years may elapse before manifestations appear. The symptoms present depend on the size of the bezoar. Frequently the symptoms comprise a sense of dragging, fullness, lump or heaviness in the epigastrium, cramplike epigastric pain and periodic attacks of vomiting. As time passes, gastritis develops as a result of the foreign body, and the [illegible] of gastritis. As the bezoar increases in size, symptoms of [illegible] with the bezoar, and [illegible] disease are present. An epigastric tumor may be palpated.

The roentgenologic diagnosis of bezoar usually is definite. When there is a history of the swallowing of hair or persimmons or other significant material, and there is present a freely movable, palpable tumor in the epigastrium, the tentative diagnosis of bezoar is justified.

Endogenous Foreign Bodies. Gallstones occasionally gain entrance into the stomach through a fistula, cholecystogastric or cholecystoduodenal. The stone may be vomited, but usually it passes into the intestine and if it proceeds beyond the lower part of the ileum, will be expelled through the rectum.

In some cases foreign bodies enter the stomach as a result of violence.

A foreign body which would pass through the normal pylorus may be retained in the stomach as a result of pyloric stenosis. In the stomach of a patient who has pyloric stenosis the surgeon may find seeds, fruit skins and masses of food detritus which cannot pass out. In some instances antacid tablets of magnesium carbonate, calcium carbonate and similar drugs may be found by the surgeon or revealed by roentgenoscopic examination.

Diseases of the Stomach Due to or Consisting of Static Mechanical Abnormality. *Prolapse of the Gastric Mucosa Through the Pylorus.* Prolapse of the gastric mucosa through the pylorus is a rare cause of gastric symptoms.

Moderate redundancy of the pyloric mucosa is common, and is without symptoms. When the prolapsing mass is large, there are gastric retention and partial pyloric obstruction. When complete prolapse into the duodenum occurs, the differentiation between pedunculated tumor and prolapsing gastric mucosa will often be impossible before surgical operation is performed. If roentgenologic examination reveals a large defect in the pyloric canal and a negative shadow in the duodenal bulb, the condition may be diagnosed correctly by the roentgenologist. However, often it may be impossible to distinguish it from pyloric ulcer, hypertrophic gastritis, or carcinoma.

Organic Hourglass Deformity of the Stomach. In an hourglass deformity of the stomach the viscus is divided into two cavities connected by a channel. This contraction occurs more frequently in women than in men. The usual cause is a healed peptic ulcer which was or is situated in the middle segment of the stomach. However, an hourglass deformity of the stomach may develop after a free perfora-

his contention that there is a parallelism between the degree of differentiation of the cells, the duration of life and the number of successful resections in the carcinomas. The prognosis varies proportionately; cancers of grade 1 are the most susceptible to resection and those of grade 4 the least favorable. However, there are notable exceptions to this rule.

Approximately one half of all gastric cancers occur in the pyloric segment and in the adjacent antrum The order of occurrence, excluding the pylorus, is the lesser curvature, the cardial end of the stomach, and the anterior and posterior walls of the body of the stomach.

The involvement of the nodes above the inner end of the left clavicle (Virchow) and in the left axilla is a demonstration of distant lymphatic permeation metastasis in carcinoma of the stomach. The thoracic duct drains the abdomen and receives tributaries from nodes in the left side of the thorax, whereas the right lymphatic duct has no direct communication with the stomach Therefore metastasis is usually limited to the left side.

Metastasis to the liver arises from lymphatic permeation along the portal vein and by the portal blood stream A sudden and diffuse enlargement of the liver by numerous nodules is probably of portal vein origin Cancerous infiltration of the lymphatics of the round ligament of the liver leads to superficial umbilical metastasis

When blood-stream embolism occurs, the lungs are often involved. Metastasis may occur also in the bones, kidneys, brain and meninges, liver, spleen and skin. Small nodules in the skin are rare and when present are late in the course of carcinoma and are a sign of widespread metastasis

Distant metastatic lesions within the abdomen causing peritoneal carcinomatosis may occur in cancer of the stomach An example of such transplantation is the palpable nodes in the rectal shelf in cases of carcinoma of the stomach

Occasionally gastric symptoms suggesting intrinsic malignant disease are due to *secondary invasion* of the stomach from a primary lesion in an adjacent organ. Lesions of the pancreas and the transverse colon are the commonest offenders

Gastric carcinoma affects all of mankind, white, yellow, red and black, savage and civilized Gastric carcinoma is rarely present in persons less than 30 years of age. Approximately three fourths of all patients who have this disease are more than 50 years old Cancer of the stomach occurs in two men for each woman so afflicted

Generally it is a safe practice to tell the patient that, in so far as is known, cancer of the stomach is not due to anything that he ever did or to anything that has been done to him

Symptoms The constitutional symptoms of gastric carcinoma are frequent early symptoms Loss of body weight, a sensation of increasing fatigue, lack of endurance or the inability to carry on the ordinary day's work may be felt before any dyspeptic phenomena occur These symptoms may or may not be accompanied by pallor Pallor in other instances may be the only reason why the patient visits the physician Occasionally, only loss of body weight is the reason for his seeking help

The number of instances of inoperable carcinoma of the stomach discovered annually among physicians, nurses and other members of the staffs of hospitals, clinics and medical schools indicates that early recognizable symptoms of gastric carcinoma are not known If the difficulty of early diagnosis of the disease were realized by physicians generally, there would be less criticism of the physician "elsewhere" for not making the diagnosis. The duration of symptoms before the patient consults a physician is usually about 6 months This duration of symptoms is estimated after manifest carcinoma is present.

In many instances of carcinoma of the stomach there are no symptoms, before metastatic lesions are discovered, that signify its presence to the physician or that indicate to the patient that all is not well In the tense person in whom a cancer of the stomach has been accidentally discovered, the history of symptoms obtained

it is often of the macrocytic type. Gastroscopic examination may be of some diagnostic value in the differential diagnosis of intragastric tumors, particularly in the differentiation between true polyposis and pseudopolyposis associated with hypertrophic gastritis

Roentgenologic and occasionally endoscopic examinations are essential to the making of a clinical diagnosis of tumor of the stomach Determination of whether or not the tumor is benign depends on histologic study after the tumor or a specimen of the tumor has been removed.

Malignant Tumors. *Carcinoma of the Stomach.* The cause of carcinoma of the stomach, like that of all other carcinomas, is unknown. The theories of the origin of gastric carcinoma embrace heredity, the irritative agents of food and drink, and the precancerous lesions

Occasionally carcinoma of the stomach occurs in several members of a family. Such familial incidence of the disease has directed attention toward heredity as a factor in its pathogenesis Carcinoma has been recorded in identical, or unioval twins. The simultaneous occurrence of a similar symmetric tumor in each of a pair of homologous (unioval) twins tends to establish a basis for assigning a genetic factor to some of these tumors Often susceptibility to cancer behaves like a recessive characteristic, and insusceptibility like a dominant characteristic

In a desire to help patients and to cure cancer of the stomach it is necessary to consider as causes of cancer of the stomach certain precancerous lesions Lesions that may precede the development of gastric cancer, particularly in middle-aged patients, are gastric ulcer, gastritis and benign tumors. It must be known, however, that there are no objective data to prove that gastric cancers are related etiologically to chronic gastritis The rarity of gastritis complicated by polypoid hyperplastic changes precludes the assumption that this condition is an important predisposing lesion of gastric malignant disease It is known, however, that some benign gastric tumors, such as leiomyoma and neurilemmoma, undergo malignant change. Gastritis is often associated with pernicious anemia Also there is present a greater susceptibility toward the development of gastric carcinoma in those who have pernicious anemia and in members of their families than in those who do not have pernicious anemia

DEFINITIONS The following types of carcinoma are described by the pathologist. simple adenocarcinoma, papillary carcinoma, colloid or gelatinous carcinoma, medullary carcinoma, and scirrhous carcinoma

Simple adenocarcinoma is intimately associated with the gastric tubules Extension of the growth often reaches the greater and lesser omenta and neighboring viscera and may invade them Metastasis to the regional lymph nodes and the liver ensues.

The term papillary is often applied to carcinoma arising in a polyp. Usually a tumor of this type is accorded a good prognosis after radical resection, since invasion of the gastric wall is rather slow and metastasis is comparatively late If metastasis occurs, it is to regional lymph nodes and the liver

The colloid or gelatinous carcinoma is an adenocarcinoma in structure, characterized by a preponderance of the mucus-producing cells, which rapidly infiltrate the muscular layer, frequently metastasizing to the regional lymph nodes and to the liver.

In the medullary type cells preponderate, connective tissue is scarce. The medullary adenocarcinoma may be diffuse and infiltrative rather than circumscribed and ulcerating Early invasion of the lymph nodes and widespread metastasis occur

The scirrhous carcinomas are of two forms, the circumscribed and the diffuse. The circumscribed type may simulate ulcer in its gross appearance

The diffuse scirrhous carcinoma often produces a shrinkage of the stomach into a rigid hollow structure, the leather bottle stomach or linitis plastica When this tumor invades the walls of the stomach they lose their pliability

Broders, believing that the extent of differentiation of the cells in the growth might prove of value in prognosis, graded malignant tumors on a basis of 1 to 4, grade 1 being the least malignant, and grade 4 the most malignant. He has many data to support

above the inner aspect of the left clavicle is present; this is often significant of cancer of the stomach However, this node may be enlarged in cancer of the urogenital tract or the mediastinum, in lymphoblastoma and, occasionally, in infectious mononucleosis, tuberculosis or syphilis. Likewise a firm enlargement of nodes beneath the lateral edge of the pectoralis major muscle or deeper in the axilla, in the absence of a similar node on the right side or of disease of the breast, may be a significant finding but in itself of little diagnostic importance. Occasionally fixation or induration of the umbilicus is observed Of the findings on physical examination that are indicative of abdominal carcinomatosis, a hard, firm, usually irregular mass palpated above the prostate gland or in a comparable position in the female is the most important This finding alone is only a diagnostic suggestion, since retroperitoneal lymphosarcoma and extension from ovarian malignant disease produce a similar hard mass in the cul-de-sac.

Analysis of gastric contents in the determination of the residuum in the stomach of a fasting person is of diagnostic importance in the presence of gastric carcinoma with pyloric obstruction. The amount of residual gastric contents may be 500 ml or even 1,000 ml or more

In 3 of every 4 instances of gastric carcinoma the ordinary analysis of the functional gastric contents reveals the degree of gastric acidity to be either achlorhydria or a definite hypochlorhydria If the roentgenoscopic study reveals an ulcer deformity, the presence of achlorhydria confirms the diagnosis of carcinoma Peptic ulcer, for practical purposes, does not exist when there is no free hydrochloric acid in the gastric contents

The presence of anemia in cancer of the stomach is variable. Before the disease has progressed to involve much of the stomach or in instances when blood loss has been of a minimal degree, there may be no anemia In an occasional patient, a macrocytic anemia may be the outstanding feature of cancer of the stomach There is evidence to indicate that polyposis and cancer of the stomach are commoner in men who have pernicious anemia than in those who do not have it Severe and progressive microcytic anemia is always a feature of advanced cancer of the stomach

Diagnosis The diagnosis of carcinoma of the stomach is made by roentgenologic examination If the first examination does not yield positive findings, a second is performed If a carcinoma near the cardia is suspected, an endoscopic examination is made

The accidental discovery of a lesion during periodic health examination or at the time of a diagnostic checkup for a previous benign lesion, such as gastric or duodenal ulcer, or the finding of the cancer at the time of operation for some other condition seems to carry no better prognostic import than those found during investigations for them Cancer thus discovered may not have been found early, and it may not be resectable Fortunately some gastric cancers are resectable and curable when the patient first realizes by some means that all is not well and that an examination is needed, and when the physician consulted immediately has a roentgenologic examination of the stomach performed by a competent roentgenologist

In regard to the course and the prognosis of cancer of the stomach during the ensuing five years after the diagnosis is made, Berkson, Walters, Gray and Priestley have analyzed their losses as shown in the diagram (Fig 13-5).

Of the total number of 100 patients diagnosed to have gastric carcinoma 14 were living at the end of 5 years Of the 86 who were not living at the end of 5 years, the lesions of 20 had been judged inoperable on examination roentgenologically and physically Thirty-six more at the time of laparotomy had been found to have nonresectable lesions. Four died in the hospital after surgical operations had been performed Twenty-six died during the 5 years following operation

in retrospect is not of diagnostic value. From such a patient it is impossible to determine the duration of symptoms before a physician was consulted. Of the nature of the symptoms which are indicative of carcinoma of the stomach it is singularly true that the gastric symptoms are new. They have never been experienced previously. They are of short duration.

The presence of local symptoms directs attention to the stomach. Often there is mild epigastric discomfort which is a feeling of fullness after a moderate meal, or there is a light cramp after dietary indiscretion Belching may be a new experience to these patients The patients usually are relieved of these discomforts by reducing the size of the meals and getting more rest. These symptoms are not considered serious because they are commonplace experiences of many middle-aged persons who do not have cancer of the stomach In those who have the disease, a distaste or dislike for certain foods, particularly meats, is a definite symptom As the disease progresses, an annoying nausea replaces this symptom, and loss of weight and weakness ensue

The nausea may be relieved by regurgitation or vomiting of small amounts of food after dietary indiscretions or after the eating of large meals. Vomiting may supersede the nausea and thus be the symptom for which relief is sought In the beginning, vomiting may occur only occasionally, the intervals between the episodes of vomiting are symptom free

In some instances of carcinoma of the stomach the illness begins with postprandial distress, which is relieved temporarily by antacids and food The patient may have taken a vacation, in the course of which these symptoms were relieved if the diet was restricted Some patients, without apparent provocation, experience gross bleeding before other local or constitutional symptoms have occurred In the presence of cancer at the cardial end of the stomach, substernal oppression, mild dysphagia, or cough may occur after the taking of food or liquids

Patients who have had dyspeptic symptoms for many years may or may not have had a change in such symptoms, an occurrence often narrated as a sure indication of early cancer These symptoms are changeable without the presence of a carcinoma

A patient may discover a lump in the epigastrium as the first symptom Large tumors in the body of the stomach may not cause local symptoms

A few patients who have gastric carcinoma are aware first of swelling of the abdomen due to ascites Backache or pathologic fractures from a metastatic lesion of the spinal column may instigate a series of roentgenologic investigations which result in the discovery of a carcinoma in the stomach

Symptoms due to a metastatic pulmonary lesion, especially of the left lung, may be of primary significance In rare instances there may be pleurisy or consolidation of this lung without any gastric symptoms though a cancer of the stomach is present and far advanced

The symptoms of pulmonary hypertension from carcinomatosis of the lung which is secondary to a primary growth in the stomach may be difficult to associate with gastric disease

Despite vicissitudes of the symptoms in early cancer of the stomach, no physician can long live at peace with his own conscience who treats a middle-aged or aging patient for any new ailment of the stomach for more than one or two weeks without a roentgenologic examination If the roentgenologist reports negative results, the examination should be repeated if symptoms persist.

Examination. Visible peristalsis occasionally occurs in early gastric carcinoma which is present at the pylorus. Epigastric tenderness is rarely found alone. A *palpable mass* varies with the somatic type of the patient, the thickness of the abdominal wall, and the site and the size of the tumor. The liver may not be enlarged or it may be irregular, firm and enlarged In an occasional instance a firm node

Diagnosis of gastric sarcoma without resort to surgical exploration and biopsy is not possible

Among patients afflicted with sarcoma, the greatest number who survive 5 years are those who have lymphosarcoma or Hodgkin's disease.

Lymphogranulomatosis and Malignant Lymphadenoma (Hodgkin's Disease) of the Stomach. The lesions of lymphoblastoma of the stomach may be situated on the lesser curvature at the cardial end and extend into the esophagus, or may involve a greater part of the stomach.

The symptoms are those of gastric malignant disease. The constitutional symptoms of Hodgkin's disease may be added Occasionally the symptoms and signs common to the abdominal type of Hodgkin's disease, such as recurring fever, diarrhea, pruritus ani et vulvae, jaundice, and ascites are present

A mass may be palpable Splenomegaly is often present when there is gastric involvement The liver is less often enlarged than the spleen. Superficial lymph nodes may be enlarged. Anemia, leukopenia, and an increase in the number of transitional cells, eosinophils, and blood platelets may be found. The roentgenologic features are not characteristic.

The diagnosis of Hodgkin's disease of the stomach is established by histologic examination If Hodgkin's disease has been diagnosed by means of biopsy of a lymph node in a patient who gives roentgenologic and gastroscopic evidence of an infiltrating lesion in the gastric wall, malignant lymphadenoma of the stomach is likely.

Linitis Plastica This condition is called also leather bottle stomach, cirrhosis of the stomach, gastritis, and granulomatosis fibroplastica, hypertrophic gastritis, gastric sclerosis, Brinton's disease, cirrhotic gastritis, and fibromatosis ventriculi

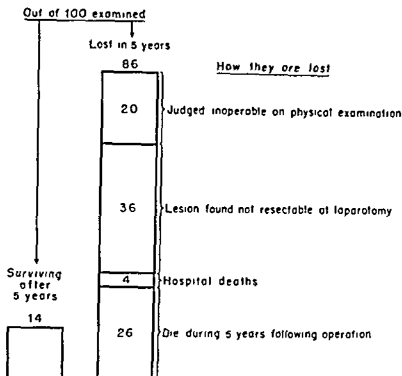
In the great majority of cases of linitis plastica the gastric disease is malignant. In a few instances linitis plastica is produced by benign affections

The gross appearance of the stomach in linitis plastica is that of a rigid, hollow viscus The walls are several times their normal thickness When the stomach is cut with a knife, it is observed to be hard The mucosa is wrinkled, nodular and uneven The peritoneum over the lesion is opaque and pearly white

The disease occurs oftenest in men from 40 to 70 years of age Women less frequently have the disease These men and women often have, in addition to their stomach trouble, cardiovascular disease, addiction to alcohol, or infection with syphilis or tuberculosis

A sensation of surfeit follows even small meals Later, postprandial fullness, belching, regurgitation and vomiting occcur Anorexia and sitophobia soon appear, and the constitutional symptoms of loss of weight, undernutrition and anemia ensue. A palpable mass in the epigastrium is present in three fourths of the patients Anemia and cachexia are common Analysis of gastric contents often reveals achlorhydria

The preoperative diagnosis of linitis plastica is based on roentgenologic study



The outlook for permanent cure after gastrectomy is uncertain, but life may be prolonged even if carcinoma is responsible for the condition If the disease is due to inflammatory processes in an individual case, a cure by gastrectomy may be obtained without the likelihood of recurrence or metastasis

PEPTIC ULCER

A peptic ulcer results from dissolution of a small region of the mucous membrane and often of the deeper coats of the stomach or the duodenum which are regularly exposed to gastric secretions

Etiology The etiologic factors of peptic ulcer which have been postulated are worthy of enumeration only because each has had serious protagonists. There are the hypothesis accusing intragastric factors as being responsible, and those accusing extragastric factors as being responsible.

In all of the various studies on series of patients who have cancer of the stomach, it is definitely revealed that the best results are obtained from resection of the stomach when metastasis has not occurred The results from surgical treatment

From Berkson J, Walters, W, Gray, H K and Priestley J T, Proc Staff Meet Mayo Clin 27 137 1952

Fig 13-5 Analysis of 5-year losses from cancer of the stomach

are not good However, surgical treatment is the only available curative procedure despite its limitations.

Sarcoma of the Stomach In only 1 per cent of the reported cases of tumors of the stomach are the growths sarcomas (Ewing) The average age at which sarcoma occurs is between 45 and 50 years, approximately 10 years less than that for gastric carcinoma

PATHOLOGY Benign connective tissue tumors are often considered to be precursors of sarcomas, particularly neurilemmomas, leiomyomas and fibromas Neurofibromas associated with Recklinghausen's disease may undergo sarcomatous change. Hodgkin's disease of the stomach may not be suspected until biopsy studies have been made.

Metastatic extension of neurogenic sarcoma, lymphosarcoma and fibrosarcoma occurs late, if at all. Myosarcomas grow rapidly and metastasize comparatively early. Blood-borne metastasis often occurs in the more malignant types of sarcoma Round cell sarcomas and endotheliomas frequently invade the blood stream Enlargement of superficial lymph nodes may occur in association with gastric lymphosarcoma, and the differential diagnosis between Hodgkin's disease, leukemia, tuberculosis and lymphosarcoma may be difficult.

Massive bleeding is the commonest complaint among patients who have leiomyosarcoma. It may occur in conjunction with other types of sarcoma after the development of necrosis and ulceration Anemia, loss of weight and strength and other constitutional symptoms occur with about the same frequency as in carcinoma of the stomach.

pancreas distort the shape of the gastric wall on healing The greatest distortion is observed when an hourglass deformity of the stomach is formed.

Although ulcers situated in the *duodenum* heal well, they usually leave some deformity, but often of minimal degree It seems that in an occasional duodenal ulcer there may be associated with the healing process a diverticulum, the so-called ulcer-diverticulum. The diverticulum is usually single, but occasionally one will develop on each curvature

Free perforation of peptic ulcer occurs most frequently from ulcers situated on the anterior wall of either the stomach or the duodenum Ulcers of the posterior wall perforate just as frequently, but into the lesser peritoneal cavity, and they often are walled off by contiguous structures which prevent free perforation.

Occult bleeding of a peptic ulcer occurs from erosion into a very small vessel or from inflammation of recently formed granulation tissue. The amount of bleeding from a peptic ulcer does not always depend on whether the blood comes from granulation tissue or from a blood vessel

SYMPTOMS Pain is the first and the only symptom of uncomplicated peptic ulcer.

The pain in peptic ulcer is originated by peristalsis, local spasm, congestion, edema and inflammatory reaction about the ulcer and not by hunger. Edema has rendered the insensitive mucosa sensitive to pain Perhaps these reactions and the situation of the ulcer are more important than the degrees of acidity present.

In gastric ulcer, after food is taken, comfort occurs, lasting from one-half to one and a half hours, followed by pain which disappears when the stomach no longer contains food In duodenal ulcer from 2 to 4 hours of comparative comfort elapse after eating; then pain appears and remains until food again is eaten or until mealtime is passed

Pain from duodenal ulcer often comes in the late evening The most characteristic time of occurrence is between midnight and 3 00 A M The patient is awakened from sleep by pain which may continue for an hour or so unless milk, warm water, or antacid is taken In many cases of duodenal ulcer no pain of consequence occurs at any other time during the entire period of ulcer activity except that coming after midnight Pain situated in the epigastrium, after midnight, which awakens the patient from sound sleep is nearly always pathognomonic of duodenal ulcer

In duodenal ulcer symptoms may commence with an attack of severe epigastric pain extending to the right costal margin or to the back Such attacks may be repeated over a period of several years before the usual symptoms of duodenal ulcer are established A rare manifestation of duodenal ulcer has been described by Eusterman as pseudotabetic crisis, in which the symptoms cannot be distinguished from the gastric crisis of tabes dorsalis Without warning, severe epigastric pain of wide radiation occurs, associated with persistent vomiting This syndrome is most often present in hypersensitive patients and comes on when they are emotionally upset In such instances it may be difficult to determine whether or not a perforation of the ulcer has occurred

During the time that a duodenal ulcer is symptomless, there may be an exacerbation of pain just for one day or one night, the interval preceding and following such exacerbation being one of pain or epigastric soreness

The syndrome of peptic ulcer is characterized by the tendency for the pain to recur *periodically* during a particular phase of the digestive cycle daily for weeks, to be followed by periods of remission of all symptoms Episodes of peptic ulcer activity are usually self-limited, regardless of treatment. Patients often give a history of daily discomfort, lasting from 3 to 6 weeks, occurring during the spring or fall months, with freedom from pain during the summer and winter seasons. Seasonal recurrences are not so often present in those who have gastric ulcer as in those who have duodenal ulcer.

Fatigue, alcoholic beverages, excessive smoking, nervous tension, exposure to

The *intragastric factors* which have been held responsible are (1) disturbances attributed to tissue-destroying and tissue-resisting influences, (2) devitalization of circumscribed areas of tissue, (3) hydrochloric acid pepsin factor, (4) lack of mucous secretion, (5) internal trauma, (6) gastritis and (7) vascular factor.

The *extragastric factors* are (1) heredity, (2) infection (focal), (3) syphilis, (4) duodenal factors, (5) nutritional deficiency, (6) burns, (7) endocrine glands, (8) allergy, (9) brain and autonomic nervous system and (10) psychosomatic relationship. These are very important.

There has never been any doubt of the preponderance of duodenal ulcer in men since the beginning of extensive gastric surgery by W. J Mayo and C H Mayo The ratio is approximately 4 men to 1 woman

The average age of the patients at the time of commencement of duodenal ulcer is between 30 and 35 years, and at onset of gastric ulcer about 40 years Peptic ulcers may occur in the newborn, in children, and during growth and early adult life.

Gastric ulcers are of a larger average size (0 5 to 4 cm.) than duodenal ulcers, which usually are about 0 5 cm in diameter Malignant gastric ulcers are usually larger (1 cm or more in diameter) than benign gastric ulcers. The size of the lesion alone cannot be used to make the differentiation between a benign ulceration and a malignant one

Gastric ulcers are often situated on the posterior wall near the lesser curvature. An occasional, usually a large, gastric ulcer is situated in the cardial zone of the stomach, near the lesser curvature Prepyloric ulcers occur A prepyloric ulcer in an aging patient is suggestive of carcinoma *Duodenal ulcers* most frequently are situated within 1½ inches (3.8 cm.) of the pyloric ring on either the anterior or [illegible] more distal segments of the duodenum.

Peptic ulcer is usually a single lesion However, two, three or more chronic gastric ulcers may be present. The gastroscopist often finds one or more smaller ulcers in association with a large chronic ulcer In about 1 of every 10 patients who have gastric ulcer a second ulcer or an ulcer deformity will be found in the duodenum. Multiple duodenal ulcers can be demonstrated in 1 of every 4 patients who have duodenal ulcer Double ulcers may occur in opposition, one situated on the anterior wall and the other on the posterior wall ("kissing ulcers")

Regularly and characteristically peptic ulcers tend to recur after complete healing has taken place. Strangely, one of two healed scars in the stomach, or one of two scars, one in the stomach and the other in the duodenum, may become reactivated while the other remains healed

PATHOLOGY Peptic ulcers occurring in either the stomach or the duodenum are classified as acute or chronic

The *acute peptic ulcers* are distinguished from erosions on the basis of depth If the erosion penetrates deeper than the muscularis mucosae, the designation acute ulcer is correct. Erosions usually are limited to the ulcer-bearing region They may be found in association with active gastric ulcer, superficial gastritis, and hypertrophic gastritis or just alone.

A *chronic peptic ulcer* is a small excavated lesion involving one or more layers of the gastric or the duodenal wall The base and wall of the ulcer are covered by mucus, fibrin and necrotic material adjacent to a fibrotic matrix which separates it from the serosa and adjacent tissues. The amount and extent of the edema present vary with the degree of activity of the ulcer

The chronic ulcers have a tendency to heal Pathologists in their examinations find an equal number of healed ulcer scars and active ulcers.

Ulcers of the *stomach* often heal without leaving visible scars and without visible deformity of the gastric wall. Often however a visible fibrotic scar remains after healing. Ulcers situated on the posterior wall of the stomach which have perforated against the

discovered by applying pressure elsewhere in the abdomen or even over the tibiae Two types of epigastric tenderness during activity of peptic ulcer have been described (1) circumscribed superficial epigastric tenderness and (2) deep tenderness The differentiation of these is of little practical value. That there is, or is not, tenderness is as far as this sign need be pursued

Genuine muscle guarding indicates serosal irritation and is observed in cases in which ulcers have deeply penetrated the wall of the viscus or have subacutely perforated it. Absolute muscular rigidity is observed only when there is free perforation with inflammation and irritation of the anterior parietal peritoneum. In such cases rebound tenderness is to be anticipated

Peristalsis may be visible in the presence of pyloric obstruction. If peristaltic movements are not visible, an exquisitely tender abdomen should not be struck to elicit them

A study of the volume of *gastric secretion* and perhaps of the *acidity* is of value in obtaining information concerning the emptying of the stomach. In clinical practice achlorhydria is not encountered in peptic ulcer A patient suspected of having a peptic ulcer should not be given histamine.

DIAGNOSIS OF PEPTIC ULCER. *Gastric Ulcer* The clinical diagnosis of peptic ulcer of the stomach from the history and the physical examination is a presumptive diagnosis A more precise diagnosis is made by the roentgenologist, who may enumerate a number of defects of the stomach which has or has had an ulcer, in addition to the ulcer itself. The terms are self-explanatory (1) organic hourglass stomach, (2) shortening and stiffening of the lesser curvature, (3) perigastric adhesions

If the symptoms are suggestive of disease within the stomach and results of roentgenologic study are negative, gastroscopic examination may be of assistance. The gastroscope may demonstrate a gastritis not revealed by roentgenoscopic examination, and may help in the differential diagnosis of benign and malignant ulcerations.

Often malignant gastric ulcers are present in cases in which there have been no ulcer symptoms Metastasis may be found by physical examination The process is evidenced by an enlarged liver, and by metastatic extension to the rectal shelf (rectovesical pouch) and supraclavicular lymph nodes In many instances an endoscopic examination is necessary for diagnosis of a malignant lesion

A gastric ulcer in a patient of 40 years of age or more is suspected of being malignant Often the roentgenologist cannot say that the ulcer is either benign or malignant.

The first help diagnostically comes from the history If there has been epigastric distress, related to the digestive cycle, extending over many years, the gastric lesion is often benign, whereas if there is a history of only recent distress, more of fullness, soreness, or aching than of a gnawing discomfort, rhythmic or constant in character, the ulcer is often malignant An added factor supporting the possibility of malignancy is a distaste for food, leading to loss of appetite There will be loss of weight in those who cannot eat

Achlorhydria, demonstrated by the ordinary fractional analysis of gastric contents, eliminates the presence of a benign peptic ulcer. If there is ample hydrochloric acid present in the gastric contents and if the niche is of the deeply penetrating type on the lesser curvature, a trial of medical therapy may be justified for diagnostic purposes If at the end of 2 or 3 weeks there is no change in the size of the niche, the lesion should be considered malignant and surgical intervention advised.

Duodenal Ulcer The history and physical examination are sufficient for presumptive diagnosis of duodenal ulcer. As in gastric ulcer, the roentgenoscopic examination is the most precise diagnostic procedure There are duodenal ulcers, however, which cannot be diagnosed by roentgenologic methods. This statement is

excessive heat or cold, or unusual physical exertion may cause an *exacerbation* of ulcer symptoms or render ulcer pain more intense, and all tend to prolong the duration of ulcer activity However, at times of unusual demands on the ulcer patient, as occasioned by excessive grief, there may be temporary amelioration of symptoms for days or even weeks, to be followed by more severe symptoms when the nervous tension is lessened

The intensity of ulcer pain is related to (1) anatomic location of the ulcer, (2) its depth and (3) inflammatory reactions. Peptic ulcers in the body or middle section of the stomach cause less pain than ulcers situated near the cardia or the pylorus The severity of the pain is more nearly related to the depth of the ulcer than to its size, and is more definitely related to the extent of the inflammatory reaction surrounding the ulcer than to any other factor. An inflammatory reaction involving the serosa produces pain of great intensity. Serosal involvement is suspected when ulcer pain becomes constant during the day and is present during the digestive cycles before, during and after meals. However, a constancy of symptoms is present when there is an accompanying gastritis or duodenitis.

Rivers observed that a shallow gastric ulcer causes a poorly localized pain, whereas definite localization occurs in one half of all patients who have large gastric ulcers with subacute inflammation Most patients who have gastric ulcers of the perforating type have localization of pain in the left upper abdominal quadrant along the costal margin When a peptic ulcer invades the mesentery, mesocolon, or abdominal wall, the pain is referred to the thorax or the back. In perforating duodenal ulcer the pain is localized in the right upper abdominal quadrant Pain due to perforations of subacute ulcers situated on the posterior wall of the duodenum is referred through to corresponding levels of the back.

In the absence of epigastric discomfort in duodenal ulcer the pain may be situated near the midline of the back between the eighth and twelfth thoracic vertebrae. Pain here does not always indicate posterior perforation; in some cases, however, it may be looked on as an indication of a perforated ulcer of the posterior duodenal wall adherent to the pancreas Occasionally ulcer discomfort is present in the lower right abdominal quadrant and has the same characteristic rhythm as if situated in the epigastrium Peptic ulcer pain may be localized to the upper right quadrant without penetration of the ulcer against the liver, pancreas, lesser omentum, or gallbladder. Duodenal or gastric ulcer may be responsible for pain localized to the anterior part of the thorax, behind the sternum between the suprasternal notch and xiphoid

The characteristic features of the discomforts and pain of uncomplicated peptic ulcer may be summarized as follows· (1) rapid relief of pain after administration of soluble alkalies, (2) amelioration, by frequent feedings of milk, of all the discomfort produced by an ulcer and (3) palliative effect on ulcer pain by physical and mental rest, relaxation, the application of warmth to the abdomen, and use of mild sedatives.

Examination On physical examination of those who have uncomplicated chronic peptic ulcers there are no findings indicative of ulcer. The value of the [illegible] diseases which may be present. [illegible] ass directs attention at once to [illegible] ric symptoms The extent and localization of tenderness, if present, are delineated and evaluated

In acute peptic ulcer or chronic peptic ulcer during an acute exacerbation of symptoms a region of circumscribed tenderness at or near the midline of the epigastrium between the xiphoid cartilage and the umbilicus may be present. However, this is of little diagnostic value, for the asthenic patient will have tenderness in the midline of the epigastrium when pressure is applied over the aorta or the ventral surface of the vertebral column. In these cases similar regions of tenderness will be

symptoms The remaining 3 will have had known symptoms, often of short duration, suggestive of peptic ulcer.

SYMPTOMS. The pain is of abrupt onset. Intelligent patients may describe a feeling of a rapid spread of the fiery sensation in the epigastric region, often as if hot water were being poured into the upper part of the abdomen The extension and the severity of the pain vary. Often the pain is centered in the epigastrium and radiates to the whole middle of the body, including the back. References of pain from this section of the body are inconsequential. In an occasional patient the generalized pain subsides somewhat, or at least the pain becomes more severe in the lower part of the abdomen, often in the lower right abdominal quadrant There seems to be a collection of the extraluminal chyme in this part of the abdomen.

The patient assumes a position with thighs flexed upon the abdomen and resents any change of position Nausea and vomiting and the characteristic facies of agony and shock supervene. The skin is cold, and is covered by perspiration The respirations are panting and shallow. The temperature is subnormal. Death rarely occurs at this time If it does occur, it follows soon and is attributed to an overwhelming effect on the vasomotor centers.

From 1 to 4 hours after the perforation there may be a period of symptomatic improvement The pain may be less intense or largely disappear; the pulse, temperature and respirations approach the normal The patient, if not restrained, may desire to sit up or walk However, on attempting such movements the intensity of the pain may return

EXAMINATION The patient may be first examined during this period of quiescent symptoms However, if on examination of the abdomen boardlike rigidity is present, operation must be performed at once The pulse rate will soon increase and the temperature will rise, malar flush will develop, and the patient becomes apprehensive because a generalized peritonitis will be present

At no time after the perforation is there any relaxation of the abdominal musculature The rigidity may be present throughout the abdomen or it may be confined to the epigastrium, with muscle guarding of lesser degree in the lower part of the abdomen Like the pain, the rigidity may develop rapidly in the lower right portion of the abdomen because of the accumulation of the gastric contents there. On auscultation there is the silent abdomen of peritonitis On percussion the hepatic dullness may be supplanted by a tympanitic or resonant note. The absence of hepatic dullness, with the patient in the dorsal decubitus, is not, however, pathognomonic of [illegible]

Digital examination of the rectum may elicit tenderness when pressure is made toward the right cul-de-sac If a firm mass is palpated in the cul-de-sac in a patient of middle life, the perforation may have resulted from the rupture of an ulcerating gastric malignant lesion

One to 4 hours [illegible] it is 10,000 to 15,000 [illegible] philia The absence [illegible] tion In elderly patients and those whose resistance is lowered from any cause, leukocytosis may be absent In due time, if operation is not performed, the leukocytes increase in number and toxic manifestations are observed in them

The blood chemical findings are not disturbed until peritonitis and vomiting are established

proved by cases in which acute perforation *has developed after* repeated roentgenograms have been recorded as negative. The clinician, however, realizes that he is held responsible for *failure to diagnose* a peptic ulcer if it perforates, irrespective of negative results of roentgenologic examination.

There are patients who have epigastric distress identical with that observed in duodenal ulcer. *This distress may be* associated with excessive use of tobacco and alcohol or it may occur *in a member of the W.C.T.U.* Often these ulcer-like manifestations are due to functional digestive disorders as a part of a state of *nervous tension incident to vagotonia.* The analysis of gastric contents discloses hyperacidity and *hypersecretion. Roentgenologic* examination does not reveal abnormality.

The diagnosis *in these cases is recorded* variously as (1) pyloroduodenal irritability, (2) pseudo-ulcer syndrome, (3) irritable duodenum, (4) pyloric spasticity, and (5) "tobacco stomach."

and [illegible]

[illegible] about the daily affairs. These symptoms usually occur in the late *afternoon. Hypoglycemia* may be suspected but it is not usually [illegible]

[illegible] cases there is hypoglycemia. This hypoglycemia may be regarded as a concomitant rather than a primary factor in the production of some of these symptoms.

Occasionally in a man who has a duodenal ulcer, the blood count, subsequent to *a moderately* severe hemorrhage, will be only slightly below the normal level. After convalescence it may be discovered that the erythrocyte count is 6,000,000 or more *per cubic millimeter* of blood. Such an erythremia is of no diagnostic importance.

Differential Diagnosis of Peptic Ulcer. The difficulty in differential diagnosis is not that of finding the ulcer when it exists, but of ascertaining the cause of the ulcer-like symptoms in the absence of ulcer. If results of the roentgenoscopic examination are negative, the examination should be followed by a period of observation and then repeated. A definite diagnosis is not made unless results of roentgenologic or gastroscopic examinations are positive.

Perforation of Peptic Ulcer. Five of every 10 patients who have gastric or duodenal ulcer, who are treated adequately under a comprehensive regimen, will become symptomless. Of the remaining 5, 4 will have recurrence; if the patients are under treatment these recurrences will be inconsequential. The remaining patient will have symptoms which are intractable, and complications will develop which require surgical intervention, often death eventuates. This last, or the 1 patient, represents the group in which the more serious complications develop, and these complications often develop during the early part of an attack and often early in the course of the *disease. Perforation* is one of these serious symptoms and hemorrhage is the other. The patient who has perforation early in the course of the disease presents greater ulcer intractability and other complications than one who has had repeated recurrences unassociated with a serious complication.

Perforation by peptic ulcer is designated as acute, subacute and chronic.

Acute Perforation. In acute perforation there is a penetration through all of the coats often of the anterior wall of the viscus, and through this opening the intraluminal contents are poured into the peritoneal cavity. Death from peritonitis and toxemia generally occurs unless surgical closure of the perforation is made immediately.

Perforation into the lesser peritoneal cavity often occurs and is generally far less hazardous than perforation into the main peritoneal cavity. These posterior perforations are usually walled off immediately.

About 1 of every 4 who have perforation of peptic ulcer has not had ulcer

Hemorrhage from Peptic Ulcer. Hemorrhage from peptic ulcer, as well as hemorrhage from other gastrointestinal disorders, has been considered under the manifestations of digestive disease at the beginning of this chapter.

Recurring Peptic Ulcer After Surgical Operation. The course of a chronic peptic ulcer is characterized by remissions and relapses The usual relapse of peptic ulcer is just that much more disability and discomfort. After surgical operation if a relapse occurs it is a more serious matter.

The recurrence of ulcer symptoms after operation may be due to the following: The original ulcer has remained unhealed, and in such instances the symptoms are exactly as they were before the operation The site of the pain and tenderness is identical with that of the original ulcer The diagnosis of duodenal ulcer is favored by the roentgenologic demonstration of a functioning pylorus unless the original active ulcer has induced spasm and edema of the pylorus so that it is closed by these processes The differentiation between recurrent duodenal ulcer subsequent to gastroenterostomy and a small jejunal ulcer may be impossible except at the time of surgical operation Ulcers rarely recur after subtotal gastric resections

Gastrojejunal and Jejunal Ulcers. The incidence of gastrojejunal ulcer is difficult to determine. It may develop following any type of operation on the stomach in which the stomach has been anastomosed to the jejunum The surgical procedures consisting of subtotal gastric resection which remove the acid-producing mucosa have reduced the incidence of postoperative gastrojejunal ulcers

A gastrojejunal ulcer is a manifestation of a continuation of all the factors which are operative in the etiology of peptic ulcer There seems to be a peptic ulcer diathesis or a gastric diathesis in some patients who have peptic ulcer Gastrojejunal ulcer occurs most frequently in patients who mistakenly feel that surgical operation cures them They have persisted in use of tobacco and alcohol, have indulged their taste for foods at irregular hours, and have continued in a state of tension and fatigue. In addition to the foregoing causes, there are gastrojejunal ulcers due to faulty technic at the time of the operation

When the stomach is anastomosed to the ileum or to the colon, the symptoms simulate those of gastrocolic fistula diarrhea, fecal vomiting, fecal odor to the eructations, loss of weight and nutritional deficiency In an occasional individual so-called miserable good health may be present for many years. The symptoms may be those of an irritable colon syndrome

A *postoperative gastritis* as cause for symptoms in the anastomotic stomach should be made by exclusion In the absence of peptic ulcer and malfunctioning stoma the symptoms are due to postoperative gastritic changes if there is a sufficient degree of gastritis present on endoscopic examination to account for the symptoms

Finding of a *free perforation* is not common in gastrojejunal ulcer

A *subacute perforation* of either a jejunal or a marginal ulcer may penetrate to the serosa and become adherent to the transverse mesocolon, the colon, the omentum, or the anterior abdominal wall with or without formation of abscess or fistula. Often a walled-off perforation of this kind can be palpated as a tender indurated soft mass in the region of the stoma When such a mass is found, surgical operation is advised

SYMPTOMS There is usually an interval of freedom from ulcer symptoms of a few months to many years after the operation This symptom-free interval may be brief or absent in cases of acute anastomotic ulcer.

Gastrojejunal ulcer often causes symptoms not unlike those of the ulcer for which the operation was performed The discomfort appears earlier after the meal. Food and antacids fail to afford the same relief which they gave previous to the operation The relief is of shorter duration and the discomfort is often more severe.

The site of the discomfort changes It is lower, generally below the umbilicus. The radiation of the pain is over a wide area, often to the back, and sometimes upward into the left pectoral region The presence of peristaltic unrest and gaseous discomfort often mimics the irritable colon syndrome

Nausea and vomiting are common and these are symptoms that were not present

DIAGNOSIS The foregoing history and physical findings are unmistakable Pneu- ... patient has an acute

... be found at surgical exploration which cannot be differentiated clinically: (1) acute fulminating appendicitis with rupture, (2) acute intestinal obstruction and (3) acute pancreatitis.

In rare instances the following conditions cannot be differentiated: (1) biliary colic, (2) renal colic, (3) twisted pedicle of an ovarian cyst, (4) ruptured ectopic gestation, (5) ruptured diverticulum of the sigmoid colon, (6) mesenteric thrombosis and (7) Meckel's diverticulum.

One condition which may resemble that of a perforated ulcer is *arachnidism*, the bite of the black widow spider Arachnidism is associated with excruciating *abdominal pain, tenderness, rigidity*, and frequent nausea and vomiting. There is usually a history of the bite about the face or on the genitalia

In a number of patients who have tabes dorsalis a gastric crisis is the initial symptom If there is a history of ulcer, a proper diagnosis is impossible. The pathognomonic neurologic findings may be absent The gastric crisis begins with a very severe epigastric pain in association with tenderness and muscle guarding but not with a permanent rigidity of the abdominal muscles The one difference may be that in most cases of gastric crisis nausea and vomiting accompany the pain. These are usually absent in perforation of ulcer, particularly in perforated duodenal ulcer. Usually the patient suffering from ulcer perforation has had ulcer-like symptoms previously. The flat plate of the roentgenologic examination will not reveal pneumoperitoneum in gastric crisis Patients in crisis do not assume and maintain the immobile position characteristic of ulcer perforation and they frequently change their positions or may even walk the floor

Even if surgical treatment is instituted immediately, perforation is still the most frequent cause of death in peptic ulcer disease The immediate mortality in perfora- ...

After recovery from the perforation and operation about half of the ... remain symptom free. For a large part of the other half of these patients symptoms and further complications may be anticipated Some patients have had subsequent perforations of peptic ulcers

Subacute Perforation. Spontaneous closure of a perforation is more often present than it is diagnosed The patient exhibits signs of perforation, but soon the symptoms abate, the rigidity disappears, the pulse, temperature and respiration *remain normal, and the rigidity of the abdominal musculature quickly* disappears If the rigidity does not disappear immediately, surgical operation is performed Even if the rigidity disappears, the process may not be over, for the localized peritonitis in the region of the perforation may originate a subphrenic, subhepatic or hepatic abscess as well as localized abscesses in the lesser peritoneal cavity. The occurrence of adhesions may cause partial obstruction of the stomach or duodenum.

The diagnosis is suspected clinically but made by roentgenologic examination

C... ... the serosa, whic... may extend into that organ or tissue Such attachments to the colon, ... der or liver, or *to the pancreas* are common If a peptic ulcer perforates at the site of the attachment to a hollow viscus, a fistula is formed. Walled-off or chronic perforations are associated with one fourth of the intractable ulcers which do not respond satisfactorily to medical treatment The occurrence of adhesions may cause partial obstruction to the outlet of the stomach or to the duodenum

The diagnosis may not be made before operation

stenosis due to peptic ulcer or carcinoma of the pylorus, in children, hypertrophic pyloric stenosis and pyloric atresia of congenital origin The uncommon causes of pyloric obstruction are: prolapse of gastric mucosa or tumor through the pylorus,

passages

Obstructing lesions distal to the papilla of Vater may produce symptoms similar to those of pyloric stenosis due to ulcer The presence of bile in large amounts in the gastric contents of a patient who has a definite gastric retention arouses suspicion that the obstruction is below the papilla of Vater

Symptoms Symptoms at the onset of organic stenosis of the pylorus in a patient who has the history of attacks of ulcer are manifested by a change in the periodicity and character of the pain The characteristic, gnawing type of discomfort of ulcer is supplanted by a feeling of epigastric fullness or heaviness which is worse soon after eating than at other times Anorexia and nausea occur together with regurgitation of the gastric contents The symptoms of pyloric obstruction commence and continue alike in both benign and malignant forms of the disease In either, almost complete obstruction with extreme dilatation of the stomach may be present. In some instances the symptoms of toxemia, malaise, lassitude, asthenia and headache will be more prominent than the symptoms of the obstruction. Retention vomiting, bad taste, anorexia, coated tongue, weakness, thirst, progressive loss of weight, oliguria, and constipation attend all forms of pyloric obstruction Hypochloremia, alkalosis and hyperazotemia ensue

The patient who has an untreated toxemia of pyloric obstruction, often, despite adequate parenteral fluids, may have twitching of the muscles of the mouth, face and extremities, muscle cramps and tetany The patient may sink slowly into a semicomatose condition and die in a state clinically resembling uremia In general, moderate grades of hypochloremia, alkalosis and hyperazotemia do not provoke subjective symptoms other than those attributed to dehydration and yield well to the parenteral administration of electrolytes and dextrose

Examination Evidence of dehydration, dryness of the tongue and skin, may be severe and may suggest uremia There may be evidence of loss of weight In half of these patients visible peristalsis is observed Tapping over the left side of the epigastrium often initiates peristaltic waves if the stomach is not greatly dilated Often a succussion splash may be elicited before breakfast If great toxemia and alkalosis are present, Chvostek's sign and Trousseau's sign may be elicited

Chemical examinations of the blood in those who have pyloric obstruction often reveal the presence of hypochloremia, alkalosis, hyperazotemia and hypopotassemia

During dehydration and alkalosis of pyloric obstruction, urinary excretion is diminished and the urine becomes strongly alkaline from the excretion of bases The excretion of bases depends to some extent on the osmotic pressure of the blood which may be further decreased by the excretion of alkali

The presence of severe dehydration and alkalosis may make it impossible for the kidneys to excrete the urea which is normally produced, so that urea gradually increases until its concentration in the blood is excessive. Hyperazotemia is usually greatest when dehydration is rapid and severe When hyperazotemia is associated with alkalosis, ketone bodies may occur in the urine

In untreated patients the concentration of chloride in the blood continues to decrease, the carbon dioxide combining power of the plasma rises steadily, and the hyperazotemia becomes progressively more severe As the carbon dioxide combining power of the plasma approaches 100 volumes per cent, tetany ensues.

Diagnosis The diagnosis of gastric retention and pyloric obstruction is made by aspiration of the fasting gastric contents and confirmed by roentgenologic exami-

before the operation. Gross hemorrhage in gastrojejunal ulcer is a common event. Melena is more common than hematemesis. Constant slow oozing of blood is the usual method of bleeding. This accounts for the presence of anemia in the patients who have anastomotic ulcer.

EXAMINATION In some patients who have postoperative peptic ulcer there may be no abdominal tenderness In those who have tenderness, it may be elicited immediately above, to the left, but most frequently below the umbilicus. The region of tenderness corresponds to the site of the pain Definite muscle guarding may be present. In some an indefinite tender mass is palpated in the lower part of the epigastrium or in the left central portion of the abdomen

The presence of true achlorhydria practically excludes the diagnosis of gastrojejunal ulcer. The fractional analysis of gastric contents also supplies valuable information concerning the emptying function of the stomach Abnormalities in emptying of the stomach are frequently found, either abnormal delay or rapid emptying

Anemia is a frequent finding

DIAGNOSIS The diagnosis of gastrojejunal ulcer depends on the history and mainly on the roentgenologic examination It may be difficult for the roentgenologist to demonstrate an abnormality in every patient who has an ulcer

In the absence of positive findings a provisional diagnosis of gastrojejunal ulcer should be made in any patient who has ulcer-like distress if a symptom-free period followed an anastomotic operation for a duodenal ulcer If the recurrence of epigastric distress has a rhythm suggestive of ulcer, and if the pain and tenderness are situated lower than those of the original ulcer, a provisional diagnosis of gastrojejunal ulcer is obligatory until it is definitely excluded. Gastroscopic examination of a patient who has undergone subtotal gastrectomy may be difficult and dangerous if attempted by untrained hands.

The prognosis of gastrojejunal ulcer is not good from the standpoint of medical treatment. Radical surgical operation including radical resection of the stomach offers the best prognosis.

Gastrojejunocolic Fistula. In perforation of gastrojejunal ulcer into the colon (gastrojejunocolic fistula) the communication may be a gastrocolic, a jejunocolic, or a gastrojejunocolic fistula These fistulas usually occur in men

The interval between surgical operation and the development of a fistula corresponds to the interval of gastrojejunal ulcer formation The fistula develops soon after the appearance of the symptoms of anastomotic ulcer

In some there are no symptoms of an anastomotic ulcer The onset of the symptoms of a fistulous communication with the colon is characterized by intestinal irritability, a tendency toward frequency and looseness of the stools, and belching of gas having a disagreeable or fecal odor If there is vomiting, the vomitus has a fecal content. Diarrhea is often severe and intractable. If the fistula is small, intestinal symptoms may be slight and intermittent The fecal matter of a patient who has a gastrojejunocolic fistula contains undigested food and increased quantities of fats and soaps Deficiency states, anemia and emaciation may come on with great rapidity as a result of the passage of the food from the stomach directly into the transverse colon. A gastrojejunocolic fistula is suspected in every patient who has undergone a gastroenterostomy and has a spruelike syndrome.

The diagnosis is established by the prompt appearance in the stomach of barium that has been injected into the colon Barium taken by mouth may enter the colon directly. In either case a roentgenogram reveals the barium where it should not be

Obstructions at the Pylorus. An obstruction at the pylorus causes limitations of mobility of the stomach and interferes with the passage of the gastric contents along to the duodenum.

The common causes of pyloric obstruction with gastric retention are. in adults,

duodenal fistula.

Rupture of the Duodenum. In rare instances a blow or crushing injury may rupture the duodenum without external evidence of injury to the abdominal wall Ruptures of the duodenum are commonly due to peptic ulceration A rupture of the duodenum is followed by shock and symptoms and signs characteristic of perforation of a peptic ulcer. The rupture of a viscus is suspected, but its location cannot be determined prior to exploratory laparotomy Plain roentgenograms of the abdomen may reveal pneumoperitoneum The prognosis in all cases of rupture of the duodenum is exceedingly poor

Periduodenitis. The symptoms of periduodenitis are those of the prevailing disease The diagnosis is made at the time of surgical operation

Chronic Duodenal Dilatation and Stasis. Chronic duodenal stasis is an uncertain clinical entity

A few of the symptoms are nausea, belching, and vomiting of bile. Gaseous indigestion, which embraces the sensations of fullness, bloating, discomfort, load or weight in the abdomen coming on after meals and associated with belching, borborygmus and increased flatulence, is present in many cases

Pain, or its equivalent, always is the major complaint Judging from the way it sometimes is described by the patient, the pain, which is situated deep in the epigastrium, closely simulates that of biliary colic Characteristically, the vomiting which is invoked by the patient gives relief

Nervous symptoms and "nervous breakdowns," anxiety, tensional states and various grades of emotional instability are often present An underlying neurosis is responsible for the loss of weight and all of the other symptoms in many of the cases in which chronic duodenal stasis is diagnosed

On examination these patients are of the somatic type having lean and slender body, arms and legs They may be immaculate in personal hygiene and dress. The abdomen is often flabby but rarely pendulous The right kidney can be palpated Tenderness is present everywhere over the body Evidence of avitaminosis and other nutritional deficiencies may be present

A clinical diagnosis of duodenal stasis, consequent to an increased mobility of the duodenum as the result of a long mesentery which permits sagging of the duodenum sufficiently to occlude its lumen, can be made only by those who believe that such a combination of aberrations of anatomy can produce symptoms. Roentgenologically and clinically, there are no definite diagnostic criteria

Carcinoma of the Duodenum. Carcinoma of the duodenum is rare, and if it occurs, the second portion of the duodenum is the most frequent site The manifestations of duodenal carcinoma depend on the situation of the tumor The presumptive diagnosis is made by the roentgenologist and confirmed by histologic study of biopsied tissue

Carcinoma of the Ampulla of Vater. Carcinoma of the ampulla of Vater may be situated in the supra-ampullary, periampullary or infra-ampullary regions

A growth in the supra-ampullary region often produces the symptoms of a duodenal ulcer Obstruction near the pylorus eventually ensues Invasion of the duodenal wall in the supra-ampullary portion may encroach on the common bile duct and main pancreatic duct, causing a progressively intense jaundice The diagnosis may be established by roentgenologic examination but more commonly is confirmed at the time of surgical exploration

A carcinoma situated close to the ampulla of Vater is often associated with intestinal bleeding and with jaundice. There may be postprandial epigastric discomfort A jaundice of fluctuating intensity associated with intestinal bleeding is

nation. The volume of the fasting gastric contents exceeds 100 ml. and may reach several liters. The stomach often contains undigested items of food taken one or more days prior to aspiration The cause of the pyloric obstruction may be determined by roentgenologic examination. The barium meal should be removed by aspiration immediately after the examination

DISEASES OF THE DUODENUM (EXCLUSIVE OF PEPTIC ULCER)

The common disease of the duodenum, peptic ulcer, has been considered. Likewise some of the important congenital anomalies have been discussed. Here will be described some diseases of the duodenum, perhaps generally regarded as rare, but real to the patients who have them.

The duodenum is composed of four portions The first portion (superior) begins at the pylorus and ends at the neck of the gallbladder. It is about 2 inches (5.1 cm) long, and runs backward along the body of the first lumbar vertebra. The second portion (descending) is about 4 inches (10 2 cm.) long, and runs down the right side of the bodies of the lumbar vertebrae to the lower border of the third vertebra. The third portion (variously called ascending, transverse or inferior) runs diagonally upward across the body of the third lumbar vertebra to its left side, and then the fourth portion ascends to the left side of the second lumbar vertebra, where it takes a sharp turn and is continued as the jejunum.

Duodenitis and Gastroduodenitis. Acute or chronic duodenitis often is but part of a widespread mucosal inflammation in either the stomach or the small intestine, or it has developed as a result of obstruction or of peptic ulcer in the duodenum It does exist alone as an entity

The term *gastroduodenitis* is employed to describe the inflammatory condition of the duodenal mucosa which may occur in association with chronic gastritis.

Duodenitis may result from direct irritation of the duodenum, as from *Ancylostoma duodenale* (hookworm), from a diverticulum, or from disease of contiguous organs

Superficial erosions appear in the duodenum in association with severe cutaneous burns, uremia, tumors of the cerebrum or midbrain, portal hypertension, or congestive heart failure or from drugs given to abate heart failure. The only definite evidence of the presence of these erosions is melena, which at times is severe In a few cases in which there are subjective symptoms, they are no different from symptoms of simple duodenal ulcer

Judd and Nagel recorded instances of duodenitis which seemed to be a separate entity. In these cases there were congestion and stippling of the serosa of the duodenum without appreciable induration of its wall. The mucosa was the seat of a circumscribed or diffuse inflammation The duodenum was not ulcerated In some cases small discrete abrasions were present. The patients, most of them aging men, all presented themselves for examination and operation for profuse and repeated gastrointestinal hemorrhages Prior to operation the results of all examinations, except for evidence of varying degrees of anemia, were negative

The diagnosis of duodenitis is established by surgical exploration, in which the duodenum is opened to determine the origin of the melena. The prognosis is good.

Tuberculosis of the Duodenum. In the late stage of tuberculosis, achlorhydria may result from gastroduodenitis Occasionally, in the ulcerative type of intestinal tuberculosis, the duodenum may be involved and, in rare instances, isolated tuberculous lesions occur in the duodenum. Tuberculosis of the duodenum may occur in association with obstructing malignant lesions. Tuberculosis of the duodenum is clinically nondiagnosable

Duodenal Fistulas. There are no symptoms referable to duodenal fistula The symptoms present are those referable to the disease conditions causing the fistula, such as perforations of the gallbladder, peptic ulcer, carcinoma of the stomach or the colon, and perforation from direct injury.

Allergy is a cause of intestinal disorders but its exact manifestations are difficult to define (see Allergic State, Chapter 18).

A failure of absorption of the intestinal chyme is present in those ill-defined conditions known as idiopathic steatorrhea, sprue and coeliac disease. It seems that in some instances a deprivation of vitamins may be due to failure of intestinal absorption. The known examples of failure of intestinal absorption are manifested by diarrhea, usually steatorrhea and a macrocytic anemia. A failure of absorption may be incident to removal of long segments of the intestines or exclusion of comparably long segments by anastomotic operations.

Pain when due to disease of the small intestines is often of intermittent character and situated about the umbilicus In disease of the colon pain is more nearly situated over the site of the disease.

The most significant manifestation of disease of the small intestine is loss of body weight In malignancy of the small intestines a rapid loss of body weight is almost always present

Diseases of the Intestines Due to Prenatal Influences. Whether or not a particular departure from the normal shape, position, size, length and state of fixation of segments or the whole of the intestine is a predisposing cause of acquired organic disease is not always possible to evaluate Many of these departures are known to be the result of congenital malformations and are without significance

That part of the intestine derived from the primitive midgut is more liable to developmental defects than any other part of the alimentary tract Congenital abnormalities are commonest (1) at or just distal to the junction of the primitive foregut and midgut, which is represented in postnatal life by the descending duodenum, (2) in the terminal ileum in the region of attachment of the embryonal omphalomesenteric duct and (3) in the cecum and ascending colon to the midtransverse colon where the primitive midgut ended

The small intestine lengthens rapidly In the embryo of 7 weeks the intestinal loop protrudes into the umbilical cord, forming a normal umbilical hernia

The large intestine grows much more slowly than the small intestine during this period In embryos of 10 weeks the abdominal cavity has grown sufficiently large so that the intestine can return The return is accomplished suddenly The small intestine is the first to re-enter the abdomen It does this in a progressive manner, the proximal portions leading, the returning coils pass behind the outstretched mesenteric artery and fill the available space on the left side of the abdomen This return of the intestine to the abdominal cavity is known as *intestinal rotation*

The large intestine is the last to leave the umbilical cord and re-enter the abdominal cavity. Its tendency to straighten, because of its thickness, then carries the cecum across to the right side of the abdomen just under the underedge of the liver, where it may remain Usually at birth, however, or by the end of the first year of life the cecum has descended to the crest of the ilium, and here it becomes fixed From this point the colon passes obliquely upward to the left of the stomach, where it recurves sharply into the future descending colon. The latter limb, remaining on the left side, forms the sigmoid segment to the midplane, where it joins the rectum As the liver loses in relative size in the enlarging abdominal cavity, a hepatic flexure appears in the originally oblique proximal limb of the colon

The ascending colon, beginning to elongate as such in the middle of fetal life, is not completed until early childhood The original cecal bulge grows and makes a definite, blind sac that extends the large intestine beyond its junction with the ileum The distal end of this sac lengthens so that the vermiform process, the appendix of the higher apes and man, becomes distinct from the cecum The cecum forms a U-shaped bend with the colon proper at 10 weeks, and this flexure with its inwardly folded walls is responsible for the ileocecal valve (valvula coli) Just distal to this valve two diverticula form and during their formation the appendix is rotated to its normal posterior position The transverse colon courses ventral to the duodenum The descending colon, like the ascend-

often due to carcinoma of the region of the papilla of Vater. On examination the gallbladder and the liver may be palpable The roentgenologic findings may be inconclusive. Anemia is usually present If gross blood is recovered from the duodenum on duodenal intubation, this may supply the first implication of the diagnosis

Carcinoma arising in the fourth portion of the duodenum, or infra-ampullary region, near the duodenojejunal junction may be manifested by the symptoms and signs of duodenal stasis On examination there is a palpable mass. The patient is pale Anemia is present. The diagnosis is established by roentgenologic examination

THE JEJUNUM AND ILEUM

(*The Small Intestine*)

The small intestine is composed of the jejunum (the empty portion of the small intestine) and the duodenum and the ileum The jejunum is about 8½ feet (2.59 meters) long and the ileum about 12½ feet (3 81 meters) They are bound to the spinal column by the mesentery, which extends from the left side of the body of the second lumbar vertebra to the right sacro-iliac joint

The jejunum and the ileum participate with the stomach, the duodenum and the colon in some acute infections such as acute gastroenterocolitis They bear the brunt of many of the diseases due to the animal parasites and often share with the colon some of the burdens of diseases of unknown causes such as ileitis and ileocolitis In addition to these diseases they have major diseases of their own Here the major diseases of the jejunum and ileum will be considered which are not described in association with diseases of the stomach, duodenum and colon

Manifestations of Disease. The manifestations of disease of the mesenteric small intestine may be enumerated as: (1) motor dysfunctions and obstruction, (2) inflammations and fevers, (3) hemorrhage, (4) allergy, (5) failures of absorption, (6) pain and (7) weight loss

Motor dysfunction may be manifested by noisy peristaltic movements—borborygmus Borborygmus often indicates a heightened peristaltic activity. If a mechanical intestinal obstruction is present there is constipation In the absence of mechanical obstruction often there is diarrhea

Diarrhea is by far the most common manifestation of disease of the intestines distal to the duodenum Diarrhea may be either acute or chronic. Acute diarrheas attend many acute infectious processes in the intestines and food poisoning The chronic diarrheas are due either to intrinsic disease of the intestines or factors extrinsic to the intestines These extrinsic factors may originate in parts of the digestive tract away from the intestines For example, may be enumerated. gastrogenous, such as that incident to achylia, achlorhydria, gastritis, gastroenterogenous fistulas, pancreatic disease, biliary tract disease, and perhaps the most common of all, the nervous diarrheas of functional origin

The intrinsic diarrheas are due to disease of the intestines. The causes for intrinsic diarrheas may be categorically arranged as follows. (1) infections which include all the agents of infection such as bacteria, viruses, and higher animal and plant parasites, (2) diseases of unknown causes such as chronic ileitis and chronic ulcerative colitis and (3) neoplasms both benign and malignant.

During the course of chronic infections and fevers there may be intestinal dysfunction The dysfunction may be due to direct involvement of the intestine by the infection or it may be due to some unknown cause related to the infection. An example of the latter may be cited: the acute episodes of diarrhea which often attend subacute or chronic bacterial endocarditis

Hemorrhage, blood appearing in the bowel motion as dark greasy black material, may be the only manifestation of ulcerative lesions or malignancy of the small intestines or proximal colon.

The diagnosis of congenital atresia is suggested by the onset of persistent vomiting immediately after birth. Roentgenograms reveal a complete obstruction of the second portion of the duodenum. Congenital atresia of the duodenum must be differentiated from congenital pyloric stenosis

Meckel's Diverticulum. This much publicized congenital outpouching of the ileum is a remnant of the omphalomesenteric duct, connecting the primitive intestine with the umbilical vesicle (Fig 13-3). This duct should close between the third and fifth weeks of fetal life. It may not close at all, and if not, a fistula remains in the abdominal wall below the umbilicus (see the Umbilicus, p. 882) through which feces may pass. An abdominal fistula may persist with the ileum in direct communication with the opening at the umbilicus The ventral fissure may close, but a blind process of the ileum persists which is united to the umbilicus by the obliterated duct represented as a solid fibrous cord

The usual deformity, however, is a persistence of the omphalomesenteric duct as a free diverticulum from the ileum This free diverticulum (Meckel's diverticulum) varies greatly in length It is situated in the ileum somewhere above the ileocecal junction and projects from the free border of the ileum The lumen may be as large as that of the ileum

Heterotopic gastric, pancreatic, or duodenal mucosa may be present in Meckel's diverticulum Aberrant gastric mucosa capable of secreting a potent gastric digestive juice is said to account for the occurrence of peptic ulcer in these pouches The ulcer is often found in the intestinal mucosa bordering on the heterotopic gastric mucosa

Symptoms are rarely caused by Meckel's diverticulum, but when present they often result from an inflammation and simulate the symptoms of appendicitis Perforation may occur and peritonitis ensue Occasionally perforation, volvulus and gangrene, or intestinal obstruction, may occur The diverticulum may become adherent within a hernial sac Hemorrhage or perforation of the peptic ulcer may occur The hemorrhage may be acute and severe or the bleeding may be repeated until severe macrocytic anemia is present Tumors such as fibrosarcomas, leiomyosarcomas, carcinomas, carcinoids and adenomas have been reported in Meckel's diverticulum

Diagnosis of a diseased Meckel's diverticulum is established by exclusion A hypochromic macrocytic anemia present in a young adult who has abdominal symptoms is suggestive of a bleeding Meckel's diverticulum The anemia may occur without other symptoms The confirmation is had at the time of surgical exploration because of indeterminate intestinal bleeding or in cases in which appendicitis is suspected Most Meckel's diverticula are found at postmortem examination and have been devoid of disease

Anomalies of Fixation. There are many departures from the average normal arrangement of intestinal attachments, especially of colonic attachments Normal functioning of the small intestine and the colon proceeds independently of position and degree of mobility

Volvulus of the Small Intestine Congenital or acquired defects of the intestine or its mesentery may contribute to the development of volvulus in the small intestine

There are several embryonic defects which are factors in producing this anomaly. Short attachment of the root of the mesentery may cause volvulus, particularly if the short attachment is in the long axis of the body The mesentery may be too long, without the usual points of fixation

The acquired defects are usually of inflammatory origin causing irregular segmental shortening of the mesentery, and they may lead to a contraction which is conducive to volvulus

In 37 cases in which operation was performed, McKechnie and Priestley listed the incidence of volvulus attributable to the various causes as follows: (1) acquired causes (26 cases), (2) congenital causes (8 cases) and (3) idiopathic (3 cases).

The distal portion of the ileum is the segment of the intestine most frequently

ing limb, is applied against the body wall and each loses its free mesentery to become fixed.

Proliferation of the epithelial lining of the duodenum leads to its occlusion in the sixth and seventh weeks, but vacuolation soon restores the lumen. The remainder of the small and all of the large intestine show a similar phenomenon, but in lesser degree

Anomalies of Rotation of the Intestines. Wide variations in the degree of nonrotation of the intestines are observed. Unless there is some deformity in addition to nonrotation which permits of or produces intestinal obstruction, nonrotation is compatible with digestive health

At the time of surgical operation inside of the abdomen or during roentgenologic study of the intestine the second part of the duodenum may be observed to turn toward the right rather than to the left, and the jejunal loops are seen in the upper right portion of the abdomen instead of in the upper left portion. It is commoner, however, to observe a failure of rotation which involves only the colon. It is presumed that in these cases the colon returns to the abdominal cavity first from the umbilical hernia

Anomalies of Position of the Intestines. No symptoms are assigned to a *duodenum* that is out of place and varies in its degree of mobility The presence of the duodenal mesentery, which permits of free mobility, often described as an inverted duodenum, likewise is free of symptoms

A double point of fixation of the duodenum, forming a redundant loop, in itself is symptomless If symptoms are present, they are due usually to a periduodenitis from a perforated ulcer

A *cecum* fixed under the liver or anywhere along the right side of the abdomen is symptomless A cecum and a *colon* all on the left side of the abdomen are likewise symptomless.

Excessively *long colons* (dolichocolons) or excessively long *sigmoidal loops* (dolichosigmoids) are symptomless

Intestinal Bands and Membranes. Congenital membranes or bands extending from the region of the gallbladder and undersurface of the liver to the proximal duodenum are seen in three forms. (1) a veil or membrane occupying the same general position as the cysticoduodenal ligament, (2) firm bands extending from the duodenal cap to the region of the anterior border of the left lobe of the liver and (3) bands extending from the superior surface of the mesocolon to the upper part of the duodenum or the pyloric region.

A congenital peritoneal band or membrane extending from the antimesenteric border of the ileum to the right iliac fossa causes a kink (*Lane's kink*) in the distal terminal ileum which may be observed by the roentgenologists Lane's kink causes no symptoms

In infants these bands, with the exception of Lane's kink, may be associated with symptoms of pyloric obstruction similar to those produced by congenital hypertrophic stenosis. There are dilatation of the stomach, visible gastric peristalsis, and emaciation A tumor is not present

The diagnosis of intestinal bands and membranes or their differentiation from periduodenal bands and congenital duodenal atresia is not possible except by surgical exploration

Congenital Atresia of the Small Intestine. Atresia may be found in any part of the small intestine. The three common sites are the second portion of the duodenum, the duodenojejunal junction, and the lower part of the ileum

Atresia of the Duodenum The common site of atresia of the duodenum is proximal to the ampulla of Vater, corresponding to the juncture of the primitive foregut and midgut, near the site of occurrence of the embryonal rotation of the small intestine. Atresia in this location may be due to the persistence of physiologic epithelial occlusion, which has been mentioned as being present normally between the first and second months of embryonal life

Diverticula of the Intestines. An intestinal diverticulum is a hernial protrusion of the mucosa of the intestine through the muscular coat.

Diverticula of the *duodenum* are of common occurrence. Duodenal diverticula are usually single, vary in size, and project from the pancreatic border of the duodenal curve in the second, third and fourth portions of the duodenum Multiple diverticula of the duodenum occur more commonly in patients who have diverticula in other segments of the alimentary tract than in those who do not

There is much evidence to support the existence of a congenital weakness in the duodenal wall which probably results from the normal process of vacuolation in the normal restoration of the lumen The larger pouches usually lack a muscular coat, although very often the smaller ones do contain some muscle fibers.

Symptoms are lacking Diagnosis is made by roentgenologic examination There is little evidence to support the diagnosis of duodenal hemorrhage from a diverticulum if peptic ulceration is not present The roentgenogram alone renders a clinical diagnosis possible but does not imply that the abdominal symptoms are due to diverticula.

Usually treatment is not necessary for these diverticula

Diverticulosis of Small Intestine. Diverticula in the small intestine are infrequent. They may occur, however, singly or multiply in the *jejunum* and in the terminal portion of the *ileum* and they vary in size

Single diverticula of the small intestine, often called pulsion diverticula, develop at points of weakness in the intestinal wall The origin of multiple diverticula is probably related to congenital faults similar to those of the duodenum These diverticula are commoner in men than in women

The symptoms of diverticula of the small intestines, if any are present, are abdominal pain, occurring at any time, fever, and low-grade intestinal obstruction indicated by abdominal distention, vomiting and constipation Bleeding may occur and at times the hemorrhage is severe Localized peritonitis occurs in some cases, and perforation of the bowel has been recorded Acute diverticulitis necessitating an emergency operation has been observed The pouch may become strangulated and gangrenous

The symptoms of intestinal diverticulosis when present are not distinctive They may simulate many other lesions The diagnosis is made by roentgenologic examination or at the time of surgical exploration

Diverticulosis of the Colon. A colonic diverticulum is the protrusion or herniation of the mucosal membrane through the muscular coat of the colon, forming a permanent sac. When outpouchings of this kind are present without being inflamed, the condition is designated diverticulosis of the colon Diverticulosis of the colon often exists indefinitely without recognizable symptoms

The cause of colonic diverticulosis is unknown At this time it is impossible to rule out a predisposing weakness in the involved part. Perhaps there is an increased intracolonic pressure in addition to the innate weakness to account for the formation of colonic diverticula

Colonic diverticula are semiglobular and communicate with the colonic lumen by necks of varying sizes The diverticula vary in size from a barely visible pouch to a sac 2 to 4 cm in diameter Diverticula rarely occur in the rectum, but the proctologist frequently views them in the distal portion of sigmoid They are situated close to the mesenteric attachment and often are confined to the appendices epiploicae and the sigmoid segment of the colon Frequently they are widely disseminated through the colon

Diverticula are in close relation to the blood vessels as the vessels pass through the muscular coat, and they may appear on the lateral and the antimesenteric aspects of the bowel The number of colonic diverticula increases as time passes.

The incidence of diverticulosis of the colon is unknown. The process of diverticularization seems to begin around the age of 40 years but persons less than the age

involved. The extent of the volvulus is limited by the degree of rotation permitted The pathologic changes are limited by the extent of injury to the mesentery.

When the circulation is grossly impaired, there are local hemorrhages, necrosis and gangrene of the bowel as the final results Peritonitis is a common complication of severe strangulation In those in whom strangulation is an early development and gangrene and perforation of the bowel follow quickly, shock, high fever, chills and general peritonitis ensue In cases in which volvulus is intermittent, the periods between complete occlusion may be marked by diarrhea In others, less than one half, obstipation is present The disease is more common in adults than in children

On examination, there are abdominal distention, tenderness and rigidity. Generally the findings are characteristic only of sudden acute intestinal obstruction These patients are often critically ill

The clinical symptoms and the findings on examination are usually not sufficient to enable one to make a preoperative diagnosis of volvulus. The diagnosis is surgical.

Volvulus of the Colon The *cecum* is commonly involved by volvulus due to congenital faults Imperfections in rotation may permit of volvulus in the newborn or in later life However, volvulus of the cecum seems to be more directly related to errors in descent and fixation of the cecum and ascending colon than to failures in rotation This does not imply that all mobile ceca will become involved in volvulus, but rather that if volvulus does occur a mobile cecum is a prerequisite.

Volvulus in the cecum commences at the point where the lack of fixation of the bowel begins The degree of rotation varies; several twists may occur Full rotation may occur without vascular occlusion The involved cecum may be found in any part of the abdomen The cecum is usually extremely distended after volvulus occurs

The symptoms of volvulus of the cecum are not characteristic. There may be pain in the lower part of the right side of the abdomen, borborygmi and constipation Chronic and recurring cecal volvulus may occur as attacks of pain in the right lower quadrant of short duration without tenderness

Examination of the abdomen in volvulus of the cecum reveals tenderness, some distention in the right lower quadrant and, in an occasional instance, a palpable mass there.

The diagnosis of volvulus of the cecum is not made prior to operation

Volvulus of the *sigmoid* often occurs when there is a long sigmoid with excessive mobility.

An abnormally long sigmoid flexure (dolichosigmoid) is frequently reported by the roentgenologist in those who have had no significant bowel trouble

Sigmoidal volvulus is rare in childhood. It occurs chiefly among elderly men In the majority of cases the patients are between 40 and 70 years of age, the average about 60 years

The onset is sudden Pain is localized to the left lower abdominal quadrant. The rectum is emptied soon after the volvulus occurs and thereafter no feces or flatus is passed Abdominal distention develops rapidly.

When the onset is acute, collapse and shock are often present In some patients, however, the symptoms may fluctuate for a number of days and then disappear. At any time during this period of fluctuation there may be a sudden transition to an illness of great severity with acute pain, abdominal distention and shock Once the acute symptoms due to volvulus have been established, there is an increasing distention and, finally, the features of peritonitis appear

On bimanual examination a tender soft pelvic mass may be palpated

The diagnosis is usually made at the time of surgical exploration

The mortality rate of surgical treatment of volvulus is high. The operative mortality in volvulus of the sigmoid is greater than in any other type of volvulus

Volvulus often recurs after operation, and often requires reoperation.

Diverticula of the Intestines. An intestinal diverticulum is a hernial protrusion of the mucosa of the intestine through the muscular coat.

Diverticula of the *duodenum* are of common occurrence. Duodenal diverticula are usually single, vary in size, and project from the pancreatic border of the duodenal curve in the second, third and fourth portions of the duodenum. Multiple diverticula of the duodenum occur more commonly in patients who have diverticula in other segments of the alimentary tract than in those who do not.

There is much evidence to support the existence of a congenital weakness in the duodenal wall which probably results from the normal process of vacuolation in the normal restoration of the lumen. The larger pouches usually lack a muscular coat, although very often the smaller ones do contain some muscle fibers

Symptoms are lacking Diagnosis is made by roentgenologic examination There is little evidence to support the diagnosis of duodenal hemorrhage from a diverticulum if peptic ulceration is not present. The roentgenogram alone renders a clinical diagnosis possible but does not imply that the abdominal symptoms are due to diverticula.

Usually treatment is not necessary for these diverticula.

Diverticulosis of Small Intestine. Diverticula in the small intestine are infrequent They may occur, however, singly or multiply in the *jejunum* and in the terminal portion of the *ileum* and they vary in size.

Single diverticula of the small intestine, often called pulsion diverticula, develop at points of weakness in the intestinal wall The origin of multiple diverticula is probably related to congenital faults similar to those of the duodenum These diverticula are commoner in men than in women.

The symptoms of diverticula of the small intestines, if any are present, are abdominal pain, occurring at any time, fever, and low-grade intestinal obstruction indicated by abdominal distention, vomiting and constipation. Bleeding may occur and at times the hemorrhage is severe Localized peritonitis occurs in some cases, and perforation of the bowel has been recorded Acute diverticulitis necessitating an emergency operation has been observed The pouch may become strangulated and gangrenous

The symptoms of intestinal diverticulosis when present are not distinctive They may simulate many other lesions The diagnosis is made by roentgenologic examination or at the time of surgical exploration.

Diverticulosis of the Colon. A colonic diverticulum is the protrusion or herniation of the mucosal membrane through the muscular coat of the colon, forming a permanent sac When outpouchings of this kind are present without being inflamed, the condition is designated diverticulosis of the colon Diverticulosis of the colon often exists indefinitely without recognizable symptoms.

The cause of colonic diverticulosis is unknown At this time it is impossible to rule out a predisposing weakness in the involved part Perhaps there is an increased intracolonic pressure in addition to the innate weakness to account for the formation of colonic diverticula.

Colonic diverticula are semiglobular and communicate with the colonic lumen by necks of varying sizes The diverticula vary in size from a barely visible pouch to a sac 2 to 4 cm in diameter. Diverticula rarely occur in the rectum, but the proctologist frequently views them in the distal portion of sigmoid. They are situated close to the mesenteric attachment and often are confined to the appendices epiploicae and the sigmoid segment of the colon Frequently they are widely disseminated through the colon.

Diverticula are in close relation to the blood vessels as the vessels pass through the muscular coat, and they may appear on the lateral and the antimesenteric aspects of the bowel The number of colonic diverticula increases as time passes

The incidence of diverticulosis of the colon is unknown The process of diverticularization seems to begin around the age of 40 years but persons less than the age

involved. The extent of the volvulus is limited by the degree of rotation permitted. The pathologic changes are limited by the extent of injury to the mesentery.

When the circulation is grossly impaired, there are local hemorrhages, necrosis and gangrene of the bowel as the final results Peritonitis is a common complication of severe strangulation In those in whom strangulation is an early development and gangrene and perforation of the bowel follow quickly, shock, high fever, chills and general peritonitis ensue In cases in which volvulus is intermittent, the periods between complete occlusion may be marked by diarrhea. In others, less than one half, obstipation is present. The disease is more common in adults than in children

On examination, there are abdominal distention, tenderness and rigidity. Generally the findings are characteristic only of sudden acute intestinal obstruction These patients are often critically ill

The clinical symptoms and the findings on examination are usually not sufficient to enable one to make a preoperative diagnosis of volvulus. The diagnosis is surgical

Volvulus of the Colon The *cecum* is commonly involved by volvulus due to congenital faults. Imperfections in rotation may permit of volvulus in the newborn or in later life However, volvulus of the cecum seems to be more directly related to errors in descent and fixation of the cecum and ascending colon than to failures in rotation This does not imply that all mobile ceca will become involved in volvulus, but rather that if volvulus does occur a mobile cecum is a prerequisite.

Volvulus in the cecum commences at the point where the lack of fixation of the bowel begins The degree of rotation varies, several twists may occur Full rotation may occur without vascular occlusion The involved cecum may be found in any part of the abdomen The cecum is usually extremely distended after volvulus occurs

The symptoms of volvulus of the cecum are not characteristic. There may be pain in the lower part of the right side of the abdomen, borborygmi and constipation Chronic and recurring cecal volvulus may occur as attacks of pain in the right lower quadrant of short duration without tenderness

Examination of the abdomen in volvulus of the cecum reveals tenderness, some distention in the right lower quadrant and, in an occasional instance, a palpable mass there

The diagnosis of volvulus of the cecum is not made prior to operation

Volvulus of the *sigmoid* often occurs when there is a long sigmoid with excessive mobility.

An abnormally long sigmoid flexure (dolichosigmoid) is frequently reported by the roentgenologist in those who have had no significant bowel trouble

Sigmoidal volvulus is rare in childhood It occurs chiefly among elderly men In the majority of cases the patients are between 40 and 70 years of age, the average about 60 years

The onset is sudden Pain is localized to the left lower abdominal quadrant. The rectum is emptied soon after the volvulus occurs and thereafter no feces or flatus is passed Abdominal distention develops rapidly.

When the onset is acute, collapse and shock are often present In some patients, however, the symptoms may fluctuate for a number of days and then disappear. At any time during this period of fluctuation there may be a sudden transition to an illness of great severity with acute pain, abdominal distention and shock Once the acute symptoms due to volvulus have been established, there is an increasing distention and, finally, the features of peritonitis appear

On bimanual examination a tender soft pelvic mass may be palpated.

The diagnosis is usually made at the time of surgical exploration

The mortality rate of surgical treatment of volvulus is high The operative mortality in volvulus of the sigmoid is greater than in any other type of volvulus

Volvulus often recurs after operation, and often requires reoperation.

vention is reserved for cases in which there are complications or sequelae or both.

According to Brown it is impossible to predict which individuals will have diverticulitis of a mild degree or which will have severe symptoms and will require surgical intervention

COMPLICATIONS OF DIVERTICULITIS OF THE COLON. The complications of diverticulitis comprise. (1) acute perforation into the free peritoneal cavity, (2) peridiverticulitis, (3) localized peritonitis, (4) abscess formation and (5) rupture of abscess with an ensuing fistula

Free perforation into the peritoneal cavity, causing acute peritonitis, is rare The signs and symptoms of a free perforation are shock, severe generalized abdominal pain, and a rigid, silent abdomen. The usual course is slow perforation with abscess formation, in which case the signs and symptoms are less severe than when free perforation is present, and there is local peritonitis Often such abscesses are absorbed In other instances the abscess enlarges sufficiently to obstruct the bowel The abscess may not obstruct the bowel but may rupture into adjacent organs and form entero-intestinal, enterovesical, or enterocutaneous fistulas. A less serious complication of diverticulitis is a scarring constriction of the lumen. This complication often follows many and repeated attacks of diverticulitis.

In some there seems to be a considerable spasm of the bowel revealed by a constriction of the colonic lumen on roentgenologic examination. These patients may have a longer convalescence from an attack than is expected It seems therefore reasonable to assume that there is considerable *peridiverticulitis* present.

Local peritonitis commonly appears in association with acute diverticulitis If the inflamed diverticulum is embedded in an epiploic appendage the latter structure may participate in the reaction, possibly contributing to the peridiverticular inflammatory reaction The presence of pus usually causes a marked change in the manifestations In addition to the fever and leukocyte response, there may be evidence of an abscess near the site of the lesion The local signs of rigidity and pain may become more marked Occasionally the abscess may rupture into the general peritoneal cavity, in which case a generalized peritonitis develops More commonly, however, the abscess becomes absorbed If resolution does not take place the abscess ruptures into a neighboring organ, for instance the intestine (entero-intestinal fistula), the bladder (enterovesical fistula), the surface of the body (enterocutaneous fistula) or the vagina (enterovaginal fistula).

The patient is often first seen on account of one or more of these complications Usually there is a preceding history of attacks of acute diverticulitis, but there may not be

On examination there are localized tenderness in the left lower abdominal quadrant and leukocytosis Soon there is a tender mass near the site of the peritoneal soiling. The local signs of rigidity and pain are definite.

As stated, *fistulas* are complications resulting from rupture of abscesses. The common fistula is a communication between the colon and the abscess cavity. The track of such a fistula is discovered on roentgenologic examination after the acute symptoms have subsided Fistulous communications are sometimes established with the urinary bladder and with other segments of the intestines (Fig. 7-2, p 403).

The *vesicocolonic fistulas* give definite symptoms. The sigmoid colon is anatomically posterior to the urinary bladder. The common site for vesicocolonic fistula from a perforated diverticulum of the colon is the posterior wall of the bladder.

The chief symptom of vesicocolonic fistula is the passage of flatus and feces through the urethra There are urinary frequency and urgency and often a burning pain in the bladder. These symptoms may or may not have been preceded by those of an existing diverticulitis. In some the diverticulitis has been troublesome prior to the vesical complication In a few men the first noticeable symptom of a vesicocolonic fistula or of the diverticulitis may be the passage of flatus through the penis.

of 30 years may have the disease. Diverticulosis seems to be about equally distributed between men and women.

Those who have diverticulosis do not belong to any one somatic type. The bowel habit prior to diverticulosis is not characteristic

There are no symptoms which can be attributed to colonic diverticulosis.

Diverticulosis is discovered in the course of a routine roentgenologic examination of the colon or at the time of abdominal operation for other intra-abdominal causes.

Diverticulitis of the Colon. Diverticulitis is inflammation of a diverticulum The symptoms of diverticulitis depend on the degree of inflammation and the nature of the complications Brown's experience indicates that in one third of those who have diverticulitis the symptoms can be attributed to inflammation, either acute or chronic, and that in two thirds they result from inflammation plus obstruction

Three fourths of patients who have diverticulitis are between the ages of 50 and 60 years when the condition is discovered. The disease affects equally both men and women There are no race exemptions

Acute Diverticulitis of the Colon Acute inflammation or acute diverticulitis may involve any portion of the colon but, like diverticulosis, it occurs most commonly in the sigmoid flexure Formerly it was called left-sided appendicitis because of certain resemblances of the signs and symptoms to those of acute appendicitis There is pain in the left lower part of the abdomen, rarely nausea or vomiting; usually the bowels are constipated

The symptoms may persist for one or two days, followed by resolution, or the process may continue and one or more of a number of complications may ensue.

The patient has fever, tenderness and muscle guarding, but rarely rigidity of the muscles There is often an increased leukocyte count

Usually if diverticulitis is present, the roentgenologist recognizes the condition by certain criteria and will report it The history and examination may be the deciding points in favor of diagnosis of diverticulitis

Recurring Diverticulitis of the Colon Recurrent attacks of acute diverticulitis almost invariably indicate the presence of some complication, the nature of which will vary in individual cases

Chronic Diverticulitis In chronic diverticulitis there is an increased interruption of the normal colonic function as a result of inflammatory reaction in the colon and contiguous structures Usually there has developed a marked inflammatory hyperplasia with partial intermittent colonic obstruction in association with adhesions A mass may be present at the site of the inflammatory reaction, usually in the lower left quadrant The signs and symptoms of low-grade intermittent obstruction may intervene. Later, in rare instances, complete colonic obstruction supervenes with all the phenomena of that condition.

DIAGNOSIS OF DIVERTICULITIS The diagnosis is usually established by roentgenologic examination However, there are instances of subacute abscess formation in which there is no other evidence of diverticular disease

The passage of gross blood in the feces in the absence of hemorrhoids and fissures is rare in diverticular disease When there is gross blood in the feces in this condition, search should be made for a coexisting polyp or a cancer

Diverticulitis and cancer are common in persons of the same age group. The occurrence of these two diseases in the same person is no more than coincidental Often a subacute perforating carcinoma of the sigmoid and diverticulosis may coexist and thus cause preoperative diagnostic difficulties. Subacute perforating diverticulitis and a subacute perforating carcinoma are both to be treated surgically Preoperative diagnosis is preferable but not always possible or essential.

The prognosis depends on the degree of disease and the success of the treatment required when the patient is first examined Basically the treatment of diverticulosis and mild diverticular disease is medical, and the prognosis is good. Surgical inter-

longitudinal ulcers also occur. The encircling tendency may account for partial intestinal obstruction Intestinal obstruction, however, is more often the result of serosal involvement with localized peritonitis and kinking of the intestine than of actual stenosis of its lumen. Peritonitis may develop as a late complication Perforation occurs most often in the ileum and next in frequency in the appendix The formation of fistula often follows operative procedures

SYMPTOMS. Often the only symptoms of a pulmonary tuberculosis are manifested by intestinal dysfunction such as an irritable colon, gastric dysfunction and anorexia

Those who know pulmonary tuberculosis and have observed its complications suspect the existence of intestinal tuberculosis if constant intestinal symptoms arise in the presence of an irregularity in the daily temperature which is not explained by the course of the pulmonary lesion and a continued unsatisfactory progress, characterized by a failure to gain weight, attended by abdominal discomforts and aberrations in regularity of bowel motions

The abdominal pain is vague, generalized, and often somewhat relieved by defecation As the condition worsens, the pain is severe. A localized, severe, constant type of pain is present when there is peritoneal irritation.

A persistent diarrhea arouses the suspicion of tuberculous involvement of the intestine in any patient who has active pulmonary tuberculosis Gross mucus, pus and blood are not commonly found in the feces Massive hemorrhage from the intestine is extremely rare.

EXAMINATION. The examination of the abdomen of a patient who has intestinal tuberculosis may not reveal abnormality With the advent of intestinal obstruction, abdominal distention occurs, and very often isolated loops of small intestine may be palpated in the abdomen or may be seen through the abdominal wall A circumscribed mass is rarely palpated in ulcerative intestinal tuberculosis

DIAGNOSIS Roentgenologic study affords the only means of clinical diagnosis of ulcerative intestinal tuberculosis prior to histologic examination and inoculation of guinea pigs with infected material.

Hypertrophic Tuberculosis This form of intestinal tuberculosis is known also as hyperplastic, nodular, scirrhous intestinal tuberculosis, neoplastic cecal tuberculosis and intestinal tuberculoma The disease frequently occurs in the absence of active pulmonary tuberculosis

Hypertrophic intestinal tuberculosis is characterized by hyperplasia of fibrous tissue and extensive thickening of the wall of the intestine with some degree of narrowing of its lumen The lesion tends to remain sharply localized

There is often an aching type of pain in the right side of the abdomen. The patient hears much gurgling of gas A bowel motion may give temporary relief from these symptoms. Pressure at times tends to relieve the pain and thus the patient discovers a mass There is some loss of weight as a result of a decreasing appetite.

On examination the tumor is hard and moderately fixed in the right side of the abdomen. Results of the rest of the examination, including that of the lungs, may be negative.

[illegible]

followed by rest and food

Intestinal Granulomas. The term granuloma designates a tumor which arises as a result of the continuous action of an irritant, provoking the formation of an excessive amount of inflammatory tissue. Intestinal granulomas are rare. There are specific granulomas, which arise during the course of an infection by a known agent, such as *Treponema pallidum*, the tubercle bacillus, or most commonly, *Endamoeba histolytica* There are nonspecific granulomas arising as the result of an unknown

Following the onset the urinary symptoms of dysuria, frequency, urgency and the passage of liquid feces may be of no great consequence or may cause severe discomfort. In time the urinary infection may become severe.

Entero-intestinal fistulas often result from perforation of the abscess back into the intestine In such case a large quantity of pus is emptied into the intestinal lumen and passed in the bowel motion. If pus is not passed with the stool, there are no other symptoms which indicate this complication These fistulas may heal spontaneously.

In women *enterovaginal fistulas* are commoner than fistulas into the bladder. Enterovaginal fistulas are manifested by the passage of gas, feces and pus from the vagina.

External fistulas rarely form anywhere else except in the vagina.

Infections of the Intestines. *Acute Enteritis.* Acute enteritis is divided into four large categories. (1) acute enteritis due to increased susceptibilities, (2) acute enteritis due to bacteria and viruses, (3) acute enteritis due to food poisoning from chemicals and (4) acute enteritis due to food poisoning from plants and animals. These conditions are described in their appropriate places in this text.

Chronic Enteritis. The diagnosis of chronic enteritis generally is a sort of escape from reality, for tuberculous enteritis, nonspecific regional enteritis, and the dysenteries are the only diagnosable diseases which fulfill any reasonable definition of chronic enteritis Despite these common observations the diagnosis of chronic enteritis often is made When such a diagnosis is assigned, it is realized that the patient has a chronic enteritis which may have originated from an addiction to alcohol which has caused chronic gastritis and finally achlorhydria and vitamin deficiency disease, or perhaps too much condiments, food roughage, or irritating medicines have been ingested. In some instances strong laxatives and cathartics have been administered for intractable constipation.

There is a chronic diarrhea of long duration associated with generalized abdominal pain or discomfort. The description of the stools is that of any stool passed as one in a series of evacuations in a day mushy, voluminous, but free from pus or blood Often excessive mucus is present.

There is no real pain. The complaint is a feeling of distention, bloating or fullness, a crampy sensation, or a feeling of moving gas Nutritional deficiencies are present in the severe instance of chronic enteritis. The results of physical examination and roentgenologic examination are negative

A diagnosis of chronic enteritis is made after ulcerative colitis, amebic colitis, *diverticulitis, polyposis and early malignant lesions, tuberculosis of the small intestine*, pernicious anemia, nontropical sprue and deficiency states, tumors, and obstructions in the small intestine have been ruled out

Tuberculosis of the Intestines. Intestinal tuberculosis occurs in two main forms, ulcerative and hypertrophic.

Ulcerative Tuberculosis This form of intestinal tuberculosis most commonly occurs in the presence of advanced pulmonary tuberculosis, and is most frequent in patients between the ages of 20 and 40 years. The incidence diminishes and the degree of involvement is less in patients more than 40 years old.

The incidence of involvement of the intestines increases as the activity of the pulmonary processes widens and as the sputum becomes filled with tubercle bacilli, which are swallowed Some phthisiologists have looked favorably upon a hematogenous pathway of infection, but the clinical evidence supports belief that the germs are swallowed.

The earliest lesions occur in Peyer's patches and in solitary lymph follicles in the wall of the intestine. The overlying mucous membrane becomes swollen and may slough, leaving an irregular-edged ulcer. Tuberculous ulcers tend to encircle the bowel, though

The cyclophyllidean tapeworms of man belong to the superfamily Taenioidea. Five families are of economic and medical importance: Anoplocephalidae, Davaineidae, Dilepididae, Hymenolepididae and Taeniidae, the last two including important parasites of man.

Dwarf Tapeworm Infection. In man this infection is caused by species *Hymenolepis nana, Hymenolepis diminuta* and *Drepanidotaenia lanceolata,* members of the family Hymenolepididae. Only the first two are of medical importance

Hymenolepis nana is a common tapeworm of man in the southern United States. It infests mice and rats also No intermediate host is required for the life cycle of this worm The infection is transmitted directly from hand to mouth

Hymenolepis diminuta produces pathologic changes similar to those caused by *Hymenolepis nana* However, *Hymenolepis diminuta* requires an intermediate host for development The natural definitive hosts of *Hymenolepis diminuta* are rats and mice. Man and dogs are accidental hosts The principal natural intermediate hosts are the rat fleas (*Ceratophyllus fasciatus* and *Xenopsylla cheopis*), which are infected in the larval stage, and the meal worm beetle (*Tenebrio molitor*).

These worms inhabit the *proximal portion* of the *ileum* without material injury to the mucosa. Light infections produce no symptoms Children who have many of these parasites may have abdominal pain with or without diarrhea, dizziness, strabismus, headache, epileptiform convulsions, and nervous disturbances. The blood may show a decrease in erythrocytes and hemoglobin, and in most instances there is an eosinophilia of from 4 to 16 per cent.

Diagnosis is based on finding the characteristic ova in the feces. The prognosis is favorable with or without treatment.

Infection with Taenia Three species of the family Taeniidae, superfamily Taenioidea, genus *Taenia,* are important parasites of man These are the pork tapeworm, *Taenia solium;* the beef tapeworm, *Taenia saginata,* and the hydatid tapeworm, *Echinococcus granulosus* The adult taenial worms are parasites of carnivorous or omnivorous animals and the larvae are parasites of herbivorous or omnivorous animals.

1. The Pork Tapeworm. Human infection with the pork tapeworm, *Taenia solium,* is especially prevalent where raw or insufficiently cooked pork is consumed. The adult parasite is extremely rare in man in the United States of America, although cysticerci are found occasionally in hogs.

The pork tapeworm requires an intermediate host for development. The ovum, usually discharged from an infected human being, contaminates the food or water ingested by a hog The freed oncosphere penetrates the intestinal wall of the hog *and develops into a cysticercus in its tissues*

Growth is rapid in the tissues of the hog and in 9 to 10 weeks the parasite is a fully developed infective worm now termed *Cysticercus cellulosae* The mature cysticercus is an ellipsoidal, translucent cyst, 10 by 5 mm , equipped with suckers and hooks If man eats this infected pork, called measly pork, the cysticercus is dissolved by the gastric juice The worm passes distally into the upper part of the small intestine, attaches itself to the intestinal wall by its evaginated scolex, and develops into an adult worm.

Occasionally man as well as other primates may act as an intermediate host, and this fact gives rise to the disease due to the larvae.

Disease Due to the Larvae of the Pork Tapeworm. Man, if he ingests the ova, may become the intermediate host for the development of *Taenia solium,* and if so, the cysticerci develop in his muscles and other tissues. This may come about by the ingestion of food or water contaminated by the ova from carriers of the adult worm, or by auto-infection through the regurgitation of ova into the stomach by reverse peristalsis In order of frequency, the larvae involve the subcutaneous tissues, brain, eyes, muscles, heart, liver, lungs and peritoneum.

irritant, infection or a foreign body inclosed in the wall of the intestine (fish bone or unabsorbed suture).

Judd expressed the belief that granulomas are often formed in adhesions to contiguous loops of bowel, the omentum, or other organs. Small abscesses and fistulous communications between loops of bowel or connecting the intestine with the body surface, urinary bladder, or vagina are common sequelae.

The causative agent, a foreign body, may frequently be found embedded deep within the lesion as a nucleus about which is a zone of inflammatory cells encircled by a thick wall of fibrous tissue.

Pain near the site of the lesion is perhaps the commonest symptom of intestinal granuloma. Chronic incomplete intestinal obstruction is often present. In many cases the long history of abdominal complaints, often intermittent in occurrence, renders the possibility of a malignant lesion remote.

Abdominal granulomas of sufficient size to produce symptoms often are associated with a palpable mass. The presence of a sinus discharging on the abdominal wall or of a mass situated immediately under a laparotomy scar should arouse a suspicion of granuloma The proctoscopic examination with biopsy will usually serve to distinguish a granuloma from a malignant lesion of the distal colon and rectum. The absence of metastasis after a mass has been known to exist for a long time often indicates a benign lesion

The feces are examined for ova and parasites. Biopsies should be made when the granulomatous lesion is accessible. The Frei antigen test is performed on all patients who have rectal lesions which are associated with stricture or granuloma.

Weber reflected that intestinal lesions of unusual roentgenologic appearance, when viewed in the light of the laboratory and clinical data, may direct one to the correct diagnosis The correct diagnosis can be established only by biopsy study The treatment is surgical.

Fecal Fistulas. Fecal fistulas occur (1) postoperatively and (2) spontaneously.

Postoperative Fecal Fistulas. Of each 10 patients who have fecal fistula which follows surgical operation, 3 will have been operated on for appendicitis. Three will have had intestinal operations for, generally, either one of two diseases: (1) regional enteritis or (2) tuberculosis Three will have had pelvic surgical intervention for either a tubo-ovarian abscess or pelvic tuberculosis, and 1 will have had an operation on the colon for diverticulitis or will have had an abscess drained which resulted from diverticulitis or chronic ulcerative colitis. There are many other causes for fecal fistulas but none so common as those just enumerated. Therefore, they are not included in this listing.

The sites of external openings of fistulous tracts, in the majority of cases, are in the right lower quadrant of the abdomen. Miscellaneous and uncommon sites are the upper part of the abdomen, posterior lumbar region, vagina, bladder and perineum. Situations of various anorectal, genitourinary and intestinal fistulas are shown in Figure 7-2, page 403.

Spontaneous Fecal Fistulas. Spontaneous [illegible] arily to abscess formation from (1) regional e[illegible] [illegible]ycosis [illegible]

[illegible] Animal Parasites. The terms helminths and vermes have been used to designate wormlike animals of three diverse phyla: (1) Platyhelminthes (flatworms), (2) Nemathelminthes (roundworms) and (3) Annelida (segmented worms). In medical parasitology all parasitic worms are collectively referred to as helminths.

Platyhelminthes (*Flatworms*). The platyhelminthes are divided into four classes of which only the Trematoda and the Cestoidea include important parasites of man.

In most instances the parasite does not evoke clinical *symptoms* other than mild chronic digestive disorders, and the presence of the worm is usually unrecognized by the patient until a segment of the worm is discovered in the feces After this discovery the symptoms are limited only by the imagination of the patient, influenced by the endless tales of folklore The most spurious symptoms are: (1) choking when hungry, the choking resulting from the worm crawling up the throat to obtain sustenance, and (2) increased hunger of the patient.

The *diagnosis* of intestinal infection depends on finding the proglottides in the feces, since the ova cannot be readily differentiated from those of *Taenia saginata*.

2. The Beef Tapeworm The life cycle of the beef tapeworm, *Taenia saginata*, is similar to that of *Taenia solium* except that the development of the cysticercus takes place in cattle instead of hogs Man is the only definitive host The cysticerci are found in cattle and have been reported infrequently from other mammals. Calves are more susceptible than older cattle. Prenatal infection in calves has been recorded The cysticercosis or larval infection has been reported in man, but in most instances identification has been somewhat uncertain.

The ova, infective when passed in the feces of man, are ingested by cattle grazing on contaminated grass On ingestion by the animal the oncospheres escape from their embryonal shell into the intestine The embryo penetrates through the intestinal wall into the lymphatics or blood vessels and reaches the intramuscular connective tissues, where it develops into a *Cysticercus bovis*. The hind limbs and hump of cattle are the selective sites, but cysticerci are also found in the heart, diaphragm, tongue and other parts of the body

When the cysticercus is ingested by man, in rare steaks or poorly cooked ground beef, it develops in the intestine into an adult worm in from 8 to 10 weeks

The adult worm causes a slight irritation of the intestinal mucosa by the mechanical action of the strobila. Usually only a single worm is present, but as many as 10 have been reported Pancreatic necrosis from the penetration of the worm into the pancreatic duct has been recorded.

Symptoms are not present until the stage is reached at which the patient observes a segment of the worm in the feces After this period there may be epigastric pain, a sinking hungry feeling, empty, gnawing sensation, and awareness of the movements of the worm. There is neither appreciable loss of weight nor increase in hunger.

The results of general examination are essentially negative. Rarely is there eosinophilia or anemia

Diagnosis is based on the recovery of the gravid proglottides or the ova in the feces. Specific diagnosis depends on the appearance of the gravid proglottis with 15 to 30 lateral uterine branches or, infrequently, on the appearance of the characteristic hookless scolex.

Prognosis is good, although it is difficult to eradicate the scolex Repeated trials by the administration of male fern, which is still the most effective vermifuge for the tapeworms, may be necessary before the scolex is obtained.

3. The Hydatid Tapeworm. Hydatid disease, hydatid cyst, is caused by *Echinococcus granulosus*, of the superfamily Taenioidea Heavy infections occur in the sheep-raising and cattle-raising districts of South America, Australia, New Zealand, South Africa, Asia, central and northern Europe, and the Mediterranean countries. Indigenous infections have occurred in North America

The definitive hosts of *Echinococcus granulosus* are dogs, wolves, jackals, coyotes and other Canidae The intermediate hosts are herbivorous animals and hogs. The larval worm is a parasite for man in regions where it is prevalent among herbivorous animals.

The ova are ingested by man and pass to the duodenum where the embryos are liberated They attach themselves by means of hooklets to the intestinal mucosa, penetrate the intestinal wall, and pass into the lymphatic or the mesenteric venous blood stream, and thus are transported to various parts of the body.

During the stage of invasion there usually are no *symptoms* unless the infection is heavy, when there may be muscular pains and mild fever.

Cerebral cysticercosis is always associated with general cysticercosis The presence of general cysticercosis is often not recognizable. Occasionally, however, cysticerci are found in the brain only. Invasion of the brain and nervous system produces grave symptoms, which do not occur until the parasite dies. On the death of the parasite the symptoms are those of intracranial hypertension, severe headaches, convulsions, epileptiform attacks and often papilledema. Contractures and motor and sensory paralyses ensue. Recurrent epileptic attacks range from petit mal with or without loss of consciousness to various stages of major epilepsy with aura. *Other cerebral manifestations* are vomiting, vertigo, muscular convulsions, hemiparesis, optic neuritis, aphasia, encephalitis, disseminated sclerosis, psychic disturbances and mental deterioration. Involvement of the spinal cord may produce hyperesthesia and altered reflexes.

Taenia solium is the commonest larval tapeworm to invade the eye, which it reaches by chance through the retinal or uveal vessels. The patient may experience infra-orbital pain, flashes of light, grotesque figures in the field of vision, and blurring and loss of vision. The cysticercus may be observed moving in the vitreous fluid.

In the eye the cysticercus, usually single and 6 to 14 mm. in size, is subretinal or in the vitreous humor, where it appears as a free or attached, elongated, light gray body The retina may be detached, the vitreous fluid slightly cloudy, the parasite surrounded by an inflammatory exudate, and the iris inflamed. Death of the parasite leads to iridocyclitis with pupillary occlusion and chemosis of the conjunctiva.

Involvement of the cardiac muscle may cause tachycardia, dyspnea, syncope and abnormal heart sounds.

On *examination* the cysticerci in the subcutaneous tissues appear as smooth, firm, oval, palpable nodules varying in size from being distinctly palpable to 1 cm. in diameter, sometimes larger. On the death of the larvae the nodules become more noticeable by an increase in fluid and an inflammatory reaction. Calcification ultimately results

In the brain cysticerci produce findings characteristic of cerebral edema, purulent meningitis, meningo-encephalitis, encephalomalacia and endarteritis. Along with or without any one or more of these manifestations may occur the topical signs and symptoms of single or multiple cortical tumors

The larvae have a peculiar affinity for the diaphragm After calcification has occurred, roentgenologic studies may reveal the presence of multiple calcified cysticerci which are accurately interpreted by the trained roentgenologist.

An eosinophilia of 5 to 12 per cent, but occasionally considerably higher, is a fairly constant but not invariable finding in cysticercosis. The feces do not contain the characteristic ova unless the cysticercosis is an instance of auto-infection

The *diagnosis* of cysticercosis is established by a biopsy of a palpable subcutaneous nodule A history of intestinal taeniasis and the presence of multiple nodules and a moderate eosinophilia are suggestive In cysticercosis of the brain and internal viscera, diagnosis is established by clinical symptoms, in the brain, perhaps by ventriculograms.

The prognosis for cysticercal infection depends on the location of the larvae. If the infection is limited to the muscles and subcutaneous tissues, the *prognosis* is favorable even with heavy infections, since the nodules in time become calcified; but if the cysticerci are present in the brain, heart or important viscera, the prognosis is grave.

Disease Due to the Adult Pork Tapeworm. The adult worm, usually a single [illegible] other than slight local [illegible] and the attachment of the scolex.

(wall-eyed pike), *Stizostedion canadense griseum* (sand pike), and *Lota maculosa* (burbot), have been found to harbor the parasite In Long Lake, Ely, Minnesota, the wall-eyed pike average 6 larvae and pickerel, 15 larvae These fish also harbor the larvae of other species of *Diphyllobothrium* that may be mistaken for *Diphyllobothrium latum*

The adult worm may produce a catarrhal condition of the intestinal mucosa Usually infection is limited to a single worm, although more may be present. *Tapeworm anemia* is more prevalent in women than in men and is most frequently observed in the spring and summer

Belding has summarized the various opinions regarding the origin of this anemia which have been advanced (1) The tapeworm is the direct cause of the anemia (2) It is a precipitating factor for an existing constitutional predisposition. (3) A true pernicious anemia may simultaneously occur in an infected individual.

There is no good evidence of a specific hematoxin created by this worm. Abortive forms of pernicious anemia can occur among patients affected. In fact, other intestinal worms at times are capable of producing a similar type of anemia.

Most persons suffer no ill effects from the fish tapeworm In a small percentage of infected persons there develops a severe *Dibothriocephalus* anemia that often hematologically resembles pernicious anemia In such instances there are the pallor, weakness, dyspnea and other symptoms characteristic of severe anemia from any cause

Unless there is evidence of an anemia present, the findings on general examination are not remarkable In those who have an anemia, the erythrocyte count varies from 1,500,000 to 3,000,000 per cubic millimeter of blood, the hemoglobin may be as low as 25 to 30 per cent The color index remains above unity (see Chapter 12). There is a leukopenia and usually, but not invariably, a more or less pronounced eosinophilia Achlorhydria is present in four fifths of these patients, and paresthesia may develop

The diagnosis is based on finding the characteristic operculate ova or the evacuated proglottides in the feces In a few instances a correct diagnosis may be suspected if the patient resides in an endemic locality, eats raw fish, and has a pernicious type of anemia

It has been common in some medical schools to ask a hypothetic question: "A fat Finnish woman, a cook by trade, has ... wer. "Fish tapeworm anemia" Jews, Russiar ... om- monly infected, and women, as stated, more frequently than men, possibly because of nibbling raw fish when preparing meals

The severest grades of anemia clear up after the successful administration of the male fern

Nemathelminthes (*Roundworms*) The Nemathelminthes of medical importance include three classes class 1, Nematoda, class 2, Nematomorpha; and class 3, Acanthocephala

Class 1 The Nematoda The nematodes are classified as belonging to the phylum Nemathelminthes that have an intestinal tract These are common but often transient parasites of man

The intestinal nematodes may maintain their positions and obtain their nutrition by temporary attachment or retention in the folds of the mucosa and by feeding on the intestinal contents (*Ascaris*) By means of an oral attachment to the intestinal mucosa some (*Ancylostoma*) may live by biting with their oral structures and ingesting blood. Some may live by anchorage with their attenuated ends and thus cause lysis of tissues for purposes of nutrition (*Trichuris*) There are those that penetrate the tissues of the intestines for nutriment Finally some (filarial worms) penetrate to the interior of the body and depend on the absorption of nourishment from the body fluid

The parasitic nematodes vary in their ability to produce mechanical ... and most of all in their ability to select ... which may be required to produce dise

Of the hydatid cysts the unilocular cysts are the common ones present in man They require several years for development. Those of great size, about 6 to 8 inches (15.2 to 20.3 cm) in diameter contain the so-called daughter cysts. Daughter cysts may arise from the germinal membrane, the brood capsules, or the scolices.

The liver is the chief site of hydatid cysts, and since the right lobe of the liver is the largest part of the organ, the most hydatid cysts will be found there. The lungs, abdominal cavity, muscles and subcutaneous tissues, kidneys, spleen and bones are often invaded, while cysts are less frequently found in the pleura, heart, brain, spinal cord, orbit and other regions

Rupture of hydatid cysts sets free scolices, bits of germinal membrane, brood capsules and daughter cysts which may reach other tissues through the blood or by direct extension and develop into secondary cysts Hepatic cysts may also rupture into the abdominal cavity, the gallbladder, biliary ducts or through the diaphragm into the pleural cavity

A hydatid cystic form termed alveolar cyst is neoplastic; it gives rise to metatasis in other organs by direct extension or through the lymphatics or the blood stream Opinions differ in regard to the origin of this cyst. The mechanism of its production is not known. An alveolar cyst has the appearance of a porous spongy mass of small irregular cavities or vesicles separated from each other by connective tissue. The alveolar hydatid is usually sterile but occasionally it contains brood capsules and scolices Calcification is often present

The osseous cysts have no regular adventitia

Infection is usually acquired during childhood, but unless the brain or the orbit is infected, symptoms do not usually appear until later in life. Most of the cases in the United States are traceable to the association with dogs, and usually the patient is of Mediterranean stock

The symptoms are those produced by a slowly growing tumor, arising in the same situation as the hydatid cyst. These symptoms are considered, in this text, with diseases of the organs in which hydatids occur.

A slight eosinophilia is present in about one half of the infected individuals. General eosinophilia occurs when there is seepage of the cystic contents. The eosinophils neutralize the toxic products of protein degradation and are essential cellular elements in hydatid allergy Precipitative and complement-fixing antibodies have been demonstrated in the blood and spinal fluid.

Clinical diagnosis is based on the presence of cystic tumors. Roentgenologic examinations are particularly useful in diagnosis and in locating cysts.

Diagnosis depends on finding the scolices, brood capsules or daughter cysts in the hydatid fluid. The exploratory puncture for the purpose of obtaining fluid is contraindicated as a dangerous diagnostic procedure since leakage may cause secondary echinococcosis and anaphylactic shock Precipitative, complement-fixation and intracutaneous tests have been used with more or less success.

The prognosis is good when the primary cyst is accessible to surgical removal.

Fish Tapeworm Infection The Superfamily Bothriocephaloidea. The cestodes of the superfamily Bothriocephaloidea, order Pseudophyllidea, that are parasites of man belong to the family Diphyllobothriidae, the members of which inhabit the intestines of mammals, birds and reptiles

Diphyllobothrium latum (*Bothriocephalus latus*, or *Dibothriocephalus latus*) causes fish tapeworm infection, known also as diphyllobothriasis, bothriocephaliasis, *Dibothriocephalus* anemia, or broad-tapeworm infection

In North America the worm has been introduced into the Great Lakes region by [illegible] There are three principal endemic areas: ([illegible] northern Minnesota and (3) the vicinity o [illegible]

The life cycle [illegible] involves two intermediate hosts, copepods and fresh-water fis[illegible] *[illegible]ostedion vitreum*

In North America four sp[illegible]

The specific invasion of the muscles is characterized by muscle stiffness, jelling and pain. *In severe infections the muscle pain and tenderness, fever, edema, cachexia* and prostration are extreme.

Symptoms occasioned by the involvement of the central nervous system are those of encephalitis: drowsiness, headache, nausea and vomiting, fever, mental confusion, disorientation, apathy, stupor, delirium, paralysis, muscular hypotonicity, diminished deep reflexes and coma. The pulmonary symptoms are those of pulmonary edema.

Death may occur when infection is intense or when resistance is low because of pre-existent weakness in vital organs In overwhelming infections it may take place *in the second or third week but more often it occurs from the fourth to the eighth* week from exhaustion, pneumonia or cardiac failure In epidemics the mortality rate may be as high as 1 death in each 3 cases of the infection.

On examination there are present a chemosis of the bulbar conjunctiva and changes in the periphery of the retina Encapsulation of larvae in the ocular muscles often takes place and there may be soreness on bulbar pressure and movements of the eyes. There are profuse sweating, rapid cardiac and respiratory rates, edema of the face, and often urticaria General muscular soreness and rheumatic pains with an inability to use the involved muscles are present, as are a feeble or a dicrotic pulse, muffled cardiac sounds, an apical systolic murmur, and palpitation. The electrocardiogram reveals evidence of myocardial damage.

The leukocyte count may range from normal to 30,000 per cubic millimeter. Eosinophilia, which appears about the fourteenth day, is a characteristic finding It ordinarily runs from 15 to 50 per cent, but may be about 75 per cent. The eosinophilia is not correlated with the severity of the disease. The eosinophilia may be low when there is a concomitant bacterial infection. It persists, for a 2 to 7 per cent eosinophilia has been found from 4 to 7 years after the disappearance of clinical symptoms Humoral immunity is evidenced by the production of precipitative and complement-fixing antibodies

Clinical diagnosis is established by the history of eating pork, the existence usually of more than one case of the disease, eosinophilia and myositis. The myositis and the demonstration of the parasites by performance of biopsy of muscle are diagnostic. The biceps, deltoid or gastrocnemius muscles are used for biopsy.

The several methods of laboratory diagnosis include (1) examination of the blood for eosinophilia, (2) the detection of adult worms in the feces and of larvae in the blood and spinal fluid and (3) the biopsy of muscles for encysted larvae.

If the patient survives for a month, recovery usually slowly ensues

2. *Trichuris trichiura.* This is one of the two species of the genus *Trichuris,* of the family Trichuridae, which are parasitic to man *Capillaria hepatica* is the other species of the worm which is parasitic

Trichuris trichiura causes *whipworm infection* The parasite maintains its position by embedding the anterior portion of its whiplike structure in the intestinal tissues of the host

The symptoms are not definite

Diagnosis is made by finding the characteristic barrel-shaped ova in the feces The worm is difficult to eradicate Prognosis is good as far as the health is concerned.

3 *Strongyloides stercoralis* Of the family Strongyloididae, superfamily Rhabditoidea, *Strongyloides stercoralis* is pathogenic for man, and causes the infection *strongyloidiasis*

Man acquires the infection usually from the soil

The infective filariform larvae penetrate the skin of the mammalian host, enter the venous circulation and pass through the right side of the heart to the lungs, *penetrate* the capillary walls into the alveoli, and ascend to the glottis, are swallowed, and reach the upper part of the intestine. By this time the worms are nearing maturity and thus they develop into adults in a short time Mature females ready for oviposition are pro-

number may overcome the resistance of any host. The local reactions are induced by both physical and chemical irritation. The reactions to these irritants comprise inflammation, necrosis, repair and encapsulation as a result of tissue sensitization and foreign body response. General reactions occur from an allergic response to foreign proteins, and indirectly from injury to vital organs.

In some individuals there is a supersensitiveness to infection which seems to be best accounted for by assuming it to be a phase of immunity that represents the reaction of the host against the proteinic products of the parasitic nematode. Supersensitiveness is manifested by both local and general reactions. Supersensitiveness may be demonstrated by cutaneous tests with antigens derived from the parasites and their products In some nematodes such diagnostic tests represent group reactions for allied species.

1. *Trichinella spiralis.* This nematode is of the family Trichinellidae, superfamily Trichuroidea The adult worms inhabit the intestine, and the larvae the muscles, of mammals and cause the disease *trichinosis.*

Trichinosis is prevalent where pork is eaten raw or insufficiently cooked, for in order to complete the life cycle of the parasite, flesh containing the encysted larvae must be ingested by another host Trichinosis occurs in Europe and in the United States of America, but is rare in Africa and South America

The incidence seems to be higher in the North Atlantic States than in other sections of the United States Trichinosis shows seasonal fluctuations, reaching its peak during the winter months when there is greater consumption of pork. In some instances, when summer sausage is ingested, epidemics of trichinosis may occur. Everywhere the disease is most frequently diagnosed or observed at necropsy.

When infected larvae are ingested by man, they pass to the small intestine where the capsules are dissolved and the larvae released The young larvae attach themselves to or invade the intestinal mucosa Within 2 days the worms reach sexual maturity and mate. After fertilization the female burrows into the mucosa of the intestinal villi and in 6 days deposits successive broods of larvae into the lymph spaces. Occasionally larvae may be liberated into the intestine.

From the lymph spaces the larvae enter the blood stream and are carried to all parts of the body.

The larvae select the tendinous portions of the muscle and soon each larva is enclosed in a capsule The processes of formation of an encapsulated larva comprise a focal acute inflammation in the muscle and degenerative changes. As a climax to many of the degenerative changes is calcification, which may begin as early as 6 months but requires months if not years for completion

During the period of larval migration the myocardium may show focal areas of interstitial cellular infiltration and at times fragmentation of the muscle fibers, fatty degeneration and necrosis.

The larvae have been found in the spinal fluid and the brain The changes in the brain are generalized hyperemia, perivascular infiltration, especially in the cortex, and granulomatous nodules around the parasite These nodules are most numerous in the basal ganglia, medulla and cerebellum.

The larvae may invade the lungs, pleura, pancreas, gallbladder, kidneys, and other organs, producing local inflammation and edema. There may be hyperplasia of bone marrow and increase of eosinophils.

The symptoms are associated with the activities of the parasites which are in- [illegible] and adult worms [illegible]

varying degrees of respiratory, ocular, and cardiac symptoms develop, and occasionally, when the fever is high, a maculopapular erythema is apparent. These symptoms may persist, characterized by fluctuation, from one to two weeks

skin. Within the body the larvae enter the blood, reach the lungs, ascend to the pharynx and pass down to the intestine where they become adults

Infection may be had by acquiring the larvae through drinking water or contaminated food.

The pathologic changes of hookworm infection comprise these in the skin at the site of entry, in the lungs, and in the small intestine, the habitat of the adult worm

There is a papulovesicular, pustular eruption at the point of penetration of the skin by the larvae.

As the migrating larvae pass into the alveolar spaces from the pulmonary capillaries, they cause petechial hemorrhages, and in heavy infections the inflammatory reaction may be so extensive and so severe as to produce a lobular pneumonia, particularly if accompanied by the secondary bacterial infection

The adult worms adhere to the intestinal mucosa with their buccal capsules, sucking blood and tearing off bits of mucosa Secondary bacterial invasion may lead to the formation of small ulcers at these sites The continuous loss of blood is the chief cause of hookworm anemia

Ground itch or hookworm dermatitis is caused by the larvae. The acute itching edematous erythema is followed by a papulovesicular eruption that may become pustular and ulcerative from pyogenic infection and may persist for weeks. Sensitive persons sometimes show urticaria

At times massive infections induce acute symptoms consisting of severe abdominal pain, sudden loss of strength, prostration, and circulatory and pulmonary disturbances. Infections with *Ancylostoma duodenale* are more serious and produce symptoms with fewer worms than infections with *Necator americanus*

Absence of symptoms occurs in those who have good health and mild infections Patients who have mild symptoms usually evidence vague dyspepsia and weakness (laziness) In more intense infections there is diarrhea with mucus and blood As a part of the anemia, there are palpitation, dyspnea and mental and physical depression The patient is listless, with apathetic puffy face and flabby muscles, and may show paresthesia, mental apathy and sexual dysfunction In severe and often fatal infections there are profound anemia, edema often with ascites, diarrhea, mental disturbances and cardiac decompensation

Infected children show physical, mental and sexual retardation Children who have fewer than 25 worms show no symptoms, with 26 to 100 a slight reduction in hemoglobin and slight mental retardation, and with more than 100, definite symptoms, namely, stunted growth, delayed sexual development, severe anemia and noticeable mental retardation

The most prominent characteristic in hookworm disease is a diminution of hemoglobin and erythrocytes The anemia begins 10 to 20 weeks after infection and is progressive It is more marked in *Ancylostoma duodenale* than in *Necator americanus* infections The erythrocytes range from 1,000,000 to 3,500,000 per cubic millimeter of blood There is a low mean corpuscular volume, a low hemoglobin and a normal or subnormal reticulocyte count. At times the blood findings are those of a macrocytic anemia

Hookworm anemia is due to the loss of blood since it may be cured by diet and iron therapy while the patient still harbors the parasites

The leukocyte count is usually from 5,200 to 10,000 per cubic millimeter, but in early infections may reach 17,000 Eosinophilia is irregular The percentage is usually from 2 to 15 per cent but during the early stages it may be as high as 55 per cent Blood cholestrol, serum protein and serum calcium are low and the glucose tolerance curve is flattened, indicating delayed absorption

Diagnosis depends on finding the characteristic ova in the feces.

Prognosis is good, except for patients in the terminal stages of the disease or those who have serious secondary complications. Recovery usually follows improved nutrition, iron therapy and administration of anthelmintics

duced in 17 or more days after the initial infection. Some of the larvae may remain in the alveolar tissues, reach adolescence in the bronchial epithelium and produce offspring that may attain the filariform stage.

An infection of the lungs and cystic duct by *Strongyloides stercoralis* is often indicative of an internal hyperinfection. Hyperinfection is brought about by the larvae developing to the filariform stage in the intestines and the skin of the perianal region and thus establishing a developmental cycle within the host.

At the site of penetration of the skin of the feet by the parasites there is intense itching. A rise of temperature, vague feelings of malaise, a slight headache and at times urticaria may ensue The migration of the larvae through the lungs may cause a febrile attack, malaise, anorexia, cough and other signs of bronchitis or sometimes symptoms of bronchopneumonia

Light infections cause no intestinal symptoms. Moderate to severe infections produce a diarrhea The general condition of the patient is usually not materially affected Prolonged infection may cause emaciation, weakness, and quick fatigue. The anemia if present is relatively slight

The general examination reveals no characteristic findings If there is a heavy pulmonary infection by the larvae, there may be the signs of bronchitis or bronchopneumonia Leukocytosis may be present during the acute infection, particularly if the lungs are involved However, as the disease becomes chronic, only a relative lymphocytosis persists Eosinophilia is usually from 10 per cent upward and at times may reach 50 per cent or more

The diagnosis depends on finding the ova in the feces. During purgation or severe dysentery embryonate ova may appear in the feces. Occasionally the ova and larvae may be found in the sputum

The prognosis is favorable except in severe cases involving hyperinfection Eradication of the worms may be difficult No known treatment is entirely satisfactory

4 *Heterodera radicicola* This nematode once was erroneously thought to be a human parasite At that time it was called *Oxyuris incognita* (family Ascaridae) because the ova were found in the feces of man, when no worms could be found Later these ova were identified as those of *Heterodera radicicola* that passed uninjured through the human intestine *Heterodera radicicola* is a parasite of the roots and stems of radishes, celery, turnips and other edible plants

5 Hookworms The species of hookworms which infest man belong to three families, Ancylostomatidae, Strongylidae and Syngamidae of the superfamily Strongyloidea

The members of the family Ancylostomatidae are parasites of the intestinal tract of mammals, and at least two species produce serious disease in man, namely, (1) *Ancylostoma duodenale* and (2) *Necator americanus* (*Uncinaria americana, Ancylostoma americanum*) Another species, *Ancylostoma braziliense*, is well known for its ability to produce ground itch, but it is incapable of producing intestinal disease in man.

The distribution of these species has been brought about by the migration of peoples *Necator americanus* is said to have been brought here by Negro slaves and immigrants, and similarly *Ancylostoma duodenale* was spread throughout the East by Chinese colonists.

The present geographic distribution of the hookworm extends in the tropical and subtropical zones between latitudes 45 degrees N and 30 degrees S, except for the presence of *Ancylostoma duodenale* in the more northerly mining districts of Europe *Necator americanus* is the prevailing species in the Western Hemisphere

Ancylostoma braziliense is a parasite of domestic and wild feline and canine animals in the tropics and subtropics It is present in Brazil and the Southern United States

The ova of all hookworms are passed in the feces, and hatch in the soil. The rhabditiform larvae grow rapidly and molt into infective filariform larvae that penetrate the

skin. Within the body the larvae enter the blood, reach the lungs, ascend to the pharynx and pass down to the intestine where they become adults.

Infection may be had by acquiring the larvae through drinking water or contaminated food

The pathologic changes of hookworm infection comprise these in the skin at the site of entry, in the lungs, and in the small intestine, the habitat of the adult worm

There is a papulovesicular, pustular eruption at the point of penetration of the skin by the larvae

As the migrating larvae pass into the alveolar spaces from the pulmonary capillaries, they cause petechial hemorrhages, and in heavy infections the inflammatory reaction may be so extensive and so severe as to produce a lobular pneumonia, particularly if accompanied by the secondary bacterial infection.

The adult worms adhere to the intestinal mucosa with their buccal capsules, sucking blood and tearing off bits of mucosa. Secondary bacterial invasion may lead to the formation of small ulcers at these sites The continuous loss of blood is the chief cause of hookworm anemia

Ground itch or hookworm dermatitis is caused by the larvae The acute itching edematous erythema is followed by a papulovesicular eruption that may become pustular and ulcerative from pyogenic infection and may persist for weeks Sensitive persons sometimes show urticaria

At times massive infections induce acute symptoms consisting of severe abdominal pain, sudden loss of strength, prostration, and circulatory and pulmonary disturbances. Infections with *Ancylostoma duodenale* are more serious and produce symptoms with fewer worms than infections with *Necator americanus*

Absence of symptoms occurs in those who have good health and mild infections Patients who have mild symptoms usually evidence vague dyspepsia and weakness (laziness) In more intense infections there is diarrhea with mucus and blood. As a part of the anemia, there are palpitation, dyspnea and mental and physical depression The patient is listless, with apathetic puffy face and flabby muscles, and may show paresthesia, mental apathy and sexual dysfunction In severe and often fatal infections there are profound anemia, edema often with ascites, diarrhea, mental disturbances and cardiac decompensation.

Infected children show physical, mental and sexual retardation Children who have fewer than 25 worms show no symptoms, with 26 to 100 a slight reduction in hemoglobin and slight mental retardation, and with more than 100, definite symptoms, namely, stunted growth, delayed sexual development, severe anemia and noticeable mental retardation

The most prominent characteristic in hookworm disease is a diminution of hemoglobin and erythrocytes. The anemia begins 10 to 20 weeks after infection and is progressive It is more marked in *Ancylostoma duodenale* than in *Necator americanus* infections The erythrocytes range from 1,000,000 to 3,500,000 per cubic millimeter of blood There is a low mean corpuscular volume, a low hemoglobin and a normal or subnormal reticulocyte count. At times the blood findings are those of a macrocytic anemia

Hookworm anemia is due to the loss of blood since it may be cured by diet and iron therapy while the patient still harbors the parasites

The leukocyte count is usually from 5,200 to 10,000 per cubic millimeter, but in early infections may reach 17,000 Eosinophilia is irregular. The percentage is usually from 2 to 15 per cent but during the early stages it may be as high as 55 per cent Blood cholestrol, serum protein and serum calcium are low and the glucose tolerance curve is flattened, indicating delayed absorption.

Diagnosis depends on finding the characteristic ova in the feces.

Prognosis is good, except for patients in the terminal stages of the disease or those who have serious secondary complications Recovery usually follows improved nutrition, iron therapy and administration of anthelmintics

6. *Ascaris lumbricoides.* This worm, of the family Ascaridae, of the superfamily Ascaroidea, infects hogs, mice, rats, rabbits and man, causing the disease *ascariasis*, a common infection.

Ingested ova hatch in the duodenum. The larvae traverse the intestinal wall until they reach the lymphatic vessels or the venules, pass to the liver, thence by the hepatic veins to the heart and ultimately to the lungs

In the lungs the larvae penetrate the capillaries to enter the alveoli Occasionally some return to the left heart through the pulmonary veins and are distributed as emboli in various parts of the body. In the lungs the growing larvae molt twice, on the fifth to sixth day and on the tenth day They migrate to the bronchi, ascend the trachea to the glottis, and pass down the esophagus, eventually reaching the intestine

The normal habitat of the adult worms is the small intestine. Their attachment to the mucosa is temporary since they are capable of moving

In the lungs the larvae set up an inflammatory process with numerous petechial hemorrhages at the site of entrance into the alveoli In severe infections there may be a lobular pneumonia.

In heavy infections intestinal obstruction with gangrene and intussusception has resulted from masses of worms

Invasion of the gallbladder and biliary tracts produces chronic irritation and inflammation of the gallbladder and obstruction of the common duct, with jaundice, pain and other symptoms of gallbladder disease

Ectopic infections have caused iritis from intra-ocular invasion by the larvae, and middle-ear disease, and ascarids have been found in the right ventricle of the heart.

Except in the presence of heavy infections there are no symptoms

The symptoms occurring during larval migration are headache, urticarial skin lesions, fever, muscular pains, coughs, dyspnea, hemoptysis and hepatic enlargement Bronchopneumonia, often fatal, occurs among children in highly endemic regions Repeated infections tend to maintain a chronic type of pulmonary infection

The commonest complaint arising from the presence of the adult worm is general abdominal discomfort with nausea, colicky pains, abnormal digestive disturbances, and loss of appetite Reflex nervous symptoms, common in young children, include irritability, colicky abdominal pains, disturbed sleep, picking at nose, grinding of teeth, and occasionally convulsions. Symptoms simulating epilepsy and meningitis have disappeared and night blindness has been cured after the removal of the worms.

Supersensitiveness may be acquired by contact and does not necessarily predicate previous infection

Examination of a patient otherwise healthy and well nourished does not reveal any findings characteristic of *Ascaris* infection In severe infections in children and debilitated starved adults there are weakness and anemia Eosinophils may reach 7 to 10 per cent of the leukocyte count

During migration of the larvae abscesses may be present in the muscles or subcutaneous tissues Bronchitis or bronchial pneumonia, hepatitis and jaundice may be found An acute hemorrhagic nephritis may be suggested by the urinary findings Abscesses of the middle ear due to the larvae may be present.

Occasionally the adult worms are passed in the feces or are regurgitated A definite diagnosis is established by finding the ova or the adult worm in the feces or in the vomitus. At times only male worms are present, hence no ova can be demonstrated In such cases diagnosis must be based on finding the adult worms. Intracutaneous and precipitative diagnostic tests are not practical

As a rule, prognosis is favorable.

Intestinal Myiasis. Intestinal myiasis in man is largely accidental, although some 30 species of dipterous larvae have been found in the digestive tract These accidental invaders are from flies that breed in decaying organic matter. The intestine, however, is the normal environment of the parasitic *Gasterophilus* larvae The larvae of the flesh flies of the genus *Sarcophaga* may gain entrance through the

anus when the eggs are deposited at the anal orifice of infants. Many larvae are destroyed by the digestive juices, but others are able to live in the intestinal tract and may produce intestinal distress (see Chapter 20).

Giardiasis or Lambliasis. *Giardia lamblia* of the family Hexamitidae resides in the proximal segments of the small intestines from the duodenum downward and in the bile ducts. This flagellate, commonly called also *Giardia intestinalis* and *Lamblia intestinalis,* is the cause of the disease *giardiasis* or *lambliasis.*

The symptoms are vague Most infected persons do not have symptoms. Those symptoms ascribed to giardial infections in adults include anorexia, headache, epigastric pain, irregular bowel movements, alternating diarrhea and constipation, nutritional disturbances, neurasthenia, anemia and fatigability. Hartman has expressed the belief that *Giardia* may give symptoms comparable to those of biliary disease and even approximate the typical syndrome of chronic cholecystitis Infections in children produce various effects, ranging from no symptoms to those of enteritis A "giardial syndrome" consisting of protracted diarrhea, gradual distention of the abdomen and retardation in growth has been described, and constipation, nervousness, fatigue and loss of appetite have been reported

Giardial infection is diagnosed by finding the cysts or occasionally the trophozoites in the feces The latter are more readily obtained by duodenal drainage, which is the most reliable method of diagnosis The distinctive structure of both trophozoite and cyst readily distinguishes *Giardia lamblia* from other intestinal flagellates.

Isospora hominis (*Coccidium hominis*) *Isospora hominis,* a species of coccidia, causes the disease termed human coccidiosis, a rare and poorly understood disorder. The pathogenicity of the organism is not definite

The oocysts which are found in the stools are probably ingested as such in food and drink, and since closely allied coccidia are found in many animals, these creatures doubtless serve as a reservoir

Diseases Due to Static or Mechanical Abnormality. ***Intestinal Obstruction.*** The term ileus is used as a synonym for intestinal obstruction When modified by the word *dynamic,* it indicates a mechanical obstruction; if by *adynamic, paralytic,* or inhibition, it denotes the absence of peristaltic activity

The incidence of the various forms of intestinal obstruction is not known Obstruction from intussusception is the commonest form in childhood Obstruction from adhesions is seen at all ages but particularly in early adult life External hernia as a cause of obstruction is also encountered in all age groups but is commonest in late middle life Old age is the period at which obstruction often is caused by carcinoma and vascular accidents such as mesenteric thrombosis.

There are forms of intestinal obstruction which often can be suspected or diagnosed prior to surgical intervention or postmortem examination

Obturation Obstruction. Sudden occlusion of the lumen of the intestine by a foreign body is a relatively rare type of ileus which is termed obturation obstruction. Obstruction of the intestinal lumen by a gallstone or by a foreign body of any kind is an example of this type of mechanical intestinal obstruction. Gallstones usually reach the bowel by passing through a fistula The commonest site of fistulization is between the gallbladder and the duodenum, or the gallbladder and the ileum Half of the stones that enter the intestine are carried along and passed spontaneously with a bowel movement

The symptoms which a gallstone or a foreign body may produce after entering the bowel depend on the size of the object and the presence of abnormalities in the bowel. In the normal intestine the commonest site of obstruction by a gallstone or

change as it passes distalward in the intestine. In some instances there are constantly present the symptoms of intestinal obstruction, beginning in the proximal portion of the intestine and shifting distally as time passes.

The variations in the symptoms in obturation ileus and the somewhat prolonged low-grade distress present prior to the development of complete obstruction contribute to the difficulty of diagnosis unless the gallstone or the foreign body can be detected by roentgenologic examination. The history in obturation ileus of swallowing an object may or may not be helpful. It is important to know that gallstone obstruction may occur in a patient who has no history of gallbladder disease or colics.

Intussusception. Intussusception is the invagination of one part of the intestine into the lumen of another part Such an occurrence is often associated with the phenomena of intestinal obstruction. Intussusception is a disease primarily of childhood, although it does occur in adults The common site for intussusception is about the ileocecal valve It may occur, however. in the ileocecal, ileocolic, enteric, and colic segments

Intestinal tumors, ulcerations, or diverticula may be present at the apex of the intussusception in adults Since most intussusceptions occur in early life in those who have no intestinal disease, primary intussusceptions are often ascribed to some such cause as an irregular action of the intestinal musculature and increased peristalsis

The injury which follows from intussusception is largely limited to the intussusceptum as the result of compression by the contractions of the intussuscipiens and by interference with its blood supply Engorgement and edema permit passage of blood and mucus into the lumen Ulceration of the intestinal wall and, as a consequence of strangulation, gangrene may ensue The gangrene often permits a slough of the prolapsed segment of the intestine A complete obstruction of the bowel often is not present in intussusception

If an intussusception is cut along its longitudinal axis to its lumen and the cut surface is viewed laterally, it is seen to consist of parallel layers consisting of the full thickness of the wall of the intestine (exemplified in a partially invaginated finger of a glove). arranged so that mucous membrane is in contact with mucous membrane and peritoneum with peritoneum The outermost layer forms the *intussuscipiens* The middle and the innermost layers comprise the *intussusceptum*, the innermost layers are the entering portion The apex of the intussusception is formed by the junction of the entering and returning layers

Symptoms Intussusception occurs either in an acute or in a chronic form The acute intussusception is common in childhood In acute intussusception abdominal pain, vomiting and the passage of blood and mucus by bowel are common symptoms Pain is sudden in its onset and occurs in paroxysms The intervals between paroxysms of pain may vary from a few minutes to a few hours in duration During these intervals there is often complete comfort There is a tendency for the pain to become somewhat less severe after the intussusception is completed

Vomiting is not a constant symptom of intussusception If present, vomiting may give temporary relief of pain

In the majority of cases of acute and subacute intussusception there is some diarrhea at first and then absolute constipation The passage of blood and mucus is rarely profuse Bloody mucus may not be passed, it may be found in the rectum on examination

Tenesmus is more commonly seen in the acute extensive ileocecal forms of intussusception than in other forms

A chronic intussusception may cause symptoms of partial intestinal obstruction or it may be present without symptoms

Examination. The significant finding on examination of the abdomen is an abdominal mass In more than half of these patients a mass can be felt on bimanual examination of the pelvis The situation of the mass is dependent on the origin and

growth of the intussusception. The intussusception may eventually reach the anus and even project from it

DIAGNOSIS The diagnosis of acute intussusception often can be made from the history and the examination. Assistance can be obtained from the use of the roentgenogram, though the barium enema may correct the defect and barium should not be administered by mouth

An acute intussusception may be simulated by simple enterocolitis, appendicitis, mesenteric thrombosis and Henoch's purpura

Prognosis depends on the treatment, which is surgical.

The mortality rate of operative reduction of intussusception is usually less than 10 per cent in patients operated on within 12 hours after the onset A mortality of more than one half occurs among patients undergoing operation later than 72 hours after the onset

The nonoperative reduction of intussusception has enthusiastic advocates The recurrences of intestinal intussusception usually are the result of some local intestinal abnormality such as polyp or diverticulum which should be surgically removed.

Volvulus. *Volvulus is an intestinal obstruction which results from a cordage* maneuver (twisting) of the bowel, often about its mesenteric axis. The directions and progression pursued by the intestine in accomplishing the twist are unknown Volvulus as a cause of intestinal obstruction occurs in about 1 of every 8 patients less than 20 years of age who have intestinal obstruction

The segments of the bowel most commonly performing volvulus are, first, the small intestine and, second, the sigmoid flexure (see Anomalies of Fixation, p 929).

Volvulus and Strangulation. Arterial obliteration occurs in volvulus but in its most exquisite form it is observed in mesenteric thrombosis or embolism. When the artery is occluded, hemorrhagic necrosis follows and plasma is lost by extravasation into the peritoneal cavity. When a medium sized vein is occluded bleeding occurs into the lumen of the intestine and blood, in large quantities, is passed in the fecal movements.

In strangulation both arterial and venous occlusion occur and there is a loss of whole blood into the wall and lumen of the bowel This loss of blood may be sufficient to account for profound shock and, in an occasional instance, death

Death may result from strangulation, gangrene, rupture of an obstructed bowel, or from the passage of infecting organisms through a devitalized intestinal wall. In high uncomplicated obstruction the resulting dehydration and disturbance of the normal chemical balances of the blood and the effects of these on the functions of various organs, notably the kidneys, may cause death (see Abdominal Apoplexy, p. 895).

Manifestations of Intestinal Obstruction. In obstruction in the proximal segments of the small intestine, vomiting is always a common symptom. When the obstruction is in the distal segments of the small intestine, vomiting is irregular and less intense In obstruction of the distal part of the small intestine, the vomitus contains colon bacilli, which impart to it a fecal odor (fecal vomiting).

As the result of the vomiting or the loss of fluid removed by nasal suction, when the obstruction occurs in the proximal part (high) of the small intestine, there ensue dehydration and alteration in the composition of the blood There is a decrease in chloride and sodium ions, and a rise in nonprotein nitrogen. Depending on the proportions of gastric juice and bile and pancreatic juice lost by vomiting, either acidosis or alkalosis may follow

When obstruction is present in the lower part of the small intestine, vomiting cannot empty the bowel Fluid and air accumulate and distention of the bowel is the prominent feature If obstruction occurs within the colon, *the tendency to distention*

pour into the colon but preventing regurgitation from the colon into the small [in]testine In this way a closed-loop type of obstruction is produced, distention be[co]mes extreme and a grave emergency *ensues requiring surgical operation.*

Reverse peristalsis and vomiting protect the intestine from the ill effects of [dis]tention Reverse peristalsis and vomiting are ineffective protective mechanisms [in t]he presence of closed-loop types of intestinal obstruction.

The local symptoms of obstruction are abdominal pain, vomiting and obstipa[tio]n. Pain is always present in an early mechanical obstruction. The pain is a true [col]ic in nonstrangulated obstruction and occurs in waves There is a free interval [bet]ween the periods of pain The pain is situated in the central part of the abdomen [wh]en the obstruction is *in the small intestine, and below the level of the umbilicus* [wh]en in the colon With each period of pain the patient is aware of the increased [per]istaltic activity and frequently feels and hears the movement of fluid and gas in [the] abdomen As distention becomes pronounced, or when the onset of strangulation [occ]urs, the discomfort becomes constant and it may be severe.

Complete obstipation is considered to be characteristic of obstruction. Complete [obs]tipation is defined as an inability to pass feces or gas after the initial enema and [a st]atement by the patient that no gas has been expelled since the enema.

EXAMINATION Evidence of increased peristaltic activity may be obtained by both [ins]pection and auscultation. Distention is more pronounced with low than with high [obs]truction and increases with the duration of the process. In high obstruction, if [vom]iting has emptied the gut, distention is absent.

Ability to hear increased peristalsis is the rule. In the normal abdomen, peristalsis [is a]udible and peristaltic rushes can often be heard. Auscultation of the abdomen [yield]s valuable information concerning the presence or the absence of intestinal [obs]truction; but only to those who have listened to a sufficient number of normal [abd]omens to evaluate what is heard in intestinal obstruction. The characteristic of [the] borborygmi heard in obstruction is their accentuated timbre during the waves of [pai]n which the patient experiences The absence of audible peristalsis is a character[isti]c feature of paralytic ileus, which is frequently a result of peritonitis

Palpation of the abdomen may yield completely negative findings in proximal [and] uncomplicated obstruction Tenderness, when present, may be of some localiz[ing] value concerning the situation of the obstruction. Palpation often gives assistance [in d]etecting the presence of intussusception, particularly in early childhood, by [feel]ing a small mass at the site of the lesion In general, palpation of a mass in the [adu]lt abdomen is not successful unless a very large tumor is present.

At the onset and after strangulation is present, the patient evinces a greater sense [of p]rostration and shock and appears much more ill than the duration of the obstruc[tion] seems to warrant Tachycardia and low blood pressure are usual

The proper interpretation of a plain posterior-anterior roentgenogram revealing [the] presence or the absence of distended loops of the intestines and their luminal [top]ography, as well as their situation in the abdomen is a most valuable examination [in i]ntestinal obstruction.

In many cases of distal intestinal obstruction the blood count remains normal. [An] increased leukocyte count is important as an indication of the presence of pos[sibl]e strangulation or leakage, and when there is an increase in the leukocyte count [wit]hout evidence of hemoconcentration, it is suggestive that strangulation has [dev]eloped.

In some instances of proximal intestinal obstruction the pronounced dehydration [du]e to *vomiting* may cause sufficient hemoconcentration to produce an elevation in [the] hemoglobin value and in both the erythrocyte and the leukocyte counts A

parallel rise in all of these values suggests that a concentration of the blood has taken place.

Changes in the blood chloride and urea nitrogen and, to a lesser degree, in the carbon dioxide combining power and the proteins of the blood, are due to the influence of the dehydration and plasma loss that occur during the course of obstruction. The determination of the concentration of these elements in the blood is of assistance in measuring the chemical imbalance. It is of no help in the diagnosis of obstruction.

DIAGNOSIS The diagnosis of acute mechanical intestinal obstruction may be obvious from the presence of cramping intermittent pain, followed by vomitus containing intestinal contents, and obstipation. In the presence of obesity, ascites and distention the plain posterior-anterior roentgenogram of the abdomen may be conclusively positive.

In many instances the finding on examination of a definite cause for one or the other type of intestinal obstruction, for instance an incarcerated hernia in mechanical obstruction, or evidence of peritonitis for a paralytic ileus, is diagnostically important.

Intestinal Obstruction Due to Disturbance of Innervation or of Psychic Control (*Paralytic Ileus and Spastic Ileus*). Paralytic ileus is due to infection or to a disturbance of innervation Spastic ileus is due to a lack of psychic control.

Paralytic Ileus Adynamic or paralytic ileus is the commonest form of intestinal obstruction and is caused usually by a general peritonitis. Intestinal function and motility cease. Paralytic ileus occurs often after abdominal operation It may commence during the course of pneumonia, empyema and septicemia Traumatic wounds, hemorrhage, spinal cord injuries, and broken bones may be attended by paralytic ileus The extravasation of blood, perforated peptic ulcer, bile peritonitis, acute pancreatitis, urogenital diseases and uremia, and lead poisoning are worsened by the presence of paralytic ileus

Paralytic ileus may involve the entire intestine. Either the small intestine or the colon, however, may be separately affected Once distention has taken place, it may continue and increase Fluid and gas rapidly accumulate in the bowel Injury to the intestine occurs as a result of distention The distention causes edema, interference with venous return, and deprives the intestine of oxygen

SYMPTOMS The chief characteristic of paralytic or adynamic ileus is the abdominal distention, often of an extreme degree There is a dull continuous ache in the distended abdomen Nausea and vomiting are prominent The vomitus is of small volume but frequent in occurrence All fluids given by mouth are regurgitated. Bowel movements and the passage of flatus cease Enemas may be only slightly effectual With great distention there is limited respiration

EXAMINATION On examination the abdomen in paralytic ileus is distended, and no single loops of bowel can be felt The presence of definite abdominal tenderness and rigidity of the abdominal wall indicates peritonitis is present When paralytic ileus is not attended by peritonitis the tenderness is usually slight and not localized and the abdominal muscles are stretched by the distention but are not tense. The percussion note is tympanitic There is complete absence of any peristaltic sound The abdomen is not "silent" because almost always an occasional tinkle can be heard The tinkle is due to movement of fluid and gas in the distended loops of bowel, the movement being caused by respiration or other movements of the body. The "silence" of one of these abdomens is further broken by the presence of the breath and heart sounds which are well transmitted through the tense abdomen.

DIAGNOSIS The forementioned physical findings are diagnostic. Roentgenologic findings also have diagnostic value

Spastic Ileus Spastic ileus is a rare form of intestinal obstruction Any portion of the intestine may be involved There may be a small ringlike band of constriction

or there may be a spastic condition of a long segment of the bowel. The sex incidence is about equal

Spastic ileus occurs in psychoneurotic individuals. The symptoms consist of colicky abdominal pain, nausea, vomiting and constipation. The history is characterized by long periods of intestinal irregularity varying from constipation to diarrhea, flatulence and abdominal discomfort. Attacks of acute pain in the lower part of the abdomen associated with profound constipation alternating with watery diarrhea are common If the attack is prolonged, abdominal distention may occur as a result of dilatation of the intestine proximal to the contraction

Examination by physical means may in every way reveal all the signs of a mechanical obstruction of the intestine The difference in these abdomens from those affected by paralytic ileus is not in the abdomen but in the behavior of the patient. The psychoneurotic strives to convince all of the degree of his suffering. The patient with paralytic ileus is preoccupied with his sufferings and examinations are clearly extra burdens for him to bear.

The general condition of patients who have functional obstruction is good as compared with that of patients who have mechanical ileus which has been present for the same period of time This observation is often of diagnostic importance. In patients who have spastic ileus of the colon roentgenologic studies are necessary in order to rule out malignant disease

The task of differential diagnosis is lessened by obtaining a history of previous attacks which have subsided spontaneously Often these patients have had many operations, sometimes 30 or 40 of them

The patient usually recovers from the attack of spastic ileus After recovery everything except surgical exploration is done to establish the absence of organic intestinal disease In some instances death may occur from an attack.

Diseases of the Intestine Due to Disorders of Metabolism. ***Intestinal Carbohydrate Dyspepsia.*** Intestinal carbohydrate dyspepsia is said to be characterized by abnormal fermentation of carbohydrate in the intestine with excessive collection of gas during which there occur recurrent episodes of abdominal distention and pain and the passage of strongly acid, gassy stools. The incidence of this symptom complex cannot be appraised. Some physicians will not make such a diagnosis; others do

There are those who think that this syndrome is rather characteristic and believe that the excessive gas formation in the small intestine results from abnormal bacterial flora, for instance, an increase in gas-forming organisms and an extension of colonic flora into the small intestine or, to the contrary, a distal extension of the fermentation of carbohydrates into the intestine There is evidence which indicates a deficiency of diastatic enzymes which may be due to salivary, pancreatic, or succus entericus deficiencies

In intestinal hypermotility Owles demonstrated that there is almost invariably some failure in the total digestion of starch, whereas the digestion of fat and muscle fibers is less affected Hypermotility of the intestine may be induced by an excessive carbohydrate intake.

Further speculation in regard to the symptom complex of intolerance for carbohydrate is the postulation that there is interference with the capacity of the small bowel to absorb gases

The symptoms are characterized by intermittent attacks of borborygmi and explosive diarrhea lasting usually a few hours. The attack often is precipitated by eating rich candy, pancakes and honey, maple syrup or any other of a long list of rich carbohydrate or starchy foods However, the attacks may recur from time to time from even small amounts of starches and sugars.

The symptoms begin from 1 to 2 hours after the meal. There are audible peristaltic rushes, terminating in from 1 to 5 or 6 bowel move

hours after meals There may be abdominal pain if diarrhea is severe. Often there are anal burning and irritation after the bowel movement

Results of physical and roentgenologic examinations are negative The blood does not show constant or characteristic abnormality

The diagnosis is usually based on the history

Diseases of the Intestines Due to Unknown Causes. *Chronic Regional Enteritis.* Chronic regional enteritis is known also as terminal or distal ileitis, chronic segmental ileitis or enteritis, and ileitis with segmental colitis and ileocolitis.

Regional enteritis is a rare disease from which no one is exempt It is said that Hebrews are a little more likely to have ileitis than gentiles There is no good evidenc [illegible] and 40 years. Sex incidence is n[illegible]le It occurs in children and particularly in adolescents more frequently than it does in the aged.

The terminal portion of the ileum, for a distance varying between several centimeters and several feet, or at irregular segmental spacing throughout the entire small intestine, appears thickened and rigid The serosal surface may be obscured by an unusual extension of mesenteric fat and fibrinous exudate The serosa proximal to the most stenotic segment of the intestine on examination reveals engorgement of vessels and various degrees of hyperemia The maximal involvement is often in the terminal portion of the ileum just proximal to its junction with the cecum

In many instances the disease continues into the proximal portion of the colon or it may skip the terminal part of the ileum and the cecum to involve the ascending or transverse segments of the colon The disease in the colon does not differ pathologically from ordinary idiopathic ulcerative colitis

The mesentery of the involved ileum is thickened, boggy and edematous Fistulization in some cases has caused a matting of various intestinal loops to each other and to other structures in the neighborhood

On opening the affected intestine, it is observed that the wall of the bowel is thickened, the lumen narrowed, and mucosal ulceration, destruction and hyperplasia are apparent

Frequently the same characteristic pathologic lesions are found situated as far proximally as the jejunum.

SYMPTOMS The most annoying symptom to the patient is diarrhea Frequently intermittent in the beginning, it becomes more nearly constant as chronicity develops, but rarely is it severe, 4 to 6 bowel motions daily being an average number Crampy abdominal pain is as regularly recurrent a symptom as the diarrhea and in many patients more disabling

The pain is situated in the midabdomen or the lower right abdominal quadrant without definite time of onset or duration Pain, often crampy, often severe, may be the only symptom Inquiry will usually reveal that there have been loss of body weight, fever and diarrhea, perhaps of a mild degree at other times in the past

A loss of body weight and strength is a constant complaint A few patients who have regional ileitis will have fever and loss of body weight and strength without any other symptoms. An occasional patient who has regional enteritis or enterocolitis will manifest nutritional deficiency which will account for the major symptoms. A few who have regional ileitis will have no significant symptoms and though not in good health, will be suffering from no great inconveniences.

Symptoms of intestinal obstruction develop in many instances. In some the symptoms of obstruction appear in the absence of significant antecedent discomforts. It is often impossible in patients who seem to have had good health to make a preoperative diagnosis of the cause for the obstruction.

A suddenly occurring free perforation with peritonitis is rarely a part of the symptomatology in regional enteritis. Perforation of the bowel which progresses slowly with abscess formation is common and a prominent cause of symptoms in

regional enteritis. The abscess may remain localized and be eventually absorbed, but often an internal fistula forms which may communicate between adjacent segments of the bowel or finally reach the outside. In some instances, however, these events may occur or may have occurred with the production of but minimal symptoms. Often there has been slight loss of body weight, a mild fever with more frequent bowel movements, and general weakness and perhaps some increase in abdominal pain

The appearance of an external fistula, particularly after an operation for appendicitis in which drainage has been established, may constitute the major complaint in regional enteritis.

Perianal and rectovaginal fistulas are often present. The manner of development is not known If a fistula-in-ano is accompanied by chronic diarrhea, ileitis is suspected

Examination. There is evidence of loss of body weight and often there are dehydration and anemia. Abdominal tenderness which is increased in the lower quadrants of the abdomen is present. Often a mass is felt in the lower right quadrant of the abdomen In the mild form of the disease the abdominal examination will be essentially negative.

The tumor in terminal regional ileitis is irregularly nodular, firm, fixed, and so tender that margins cannot be delineated In some instances of the disease signs of intestinal obstruction will be present Physical signs of nutritional deficiency such as edema of hypoproteinemia and dermatitis indicate the chronicity of the disease

In many there will be present fever and an inflammatory mass in the lower right quadrant of the abdomen. The patient may be sufficiently ill at the time of the examination that time and special consideration may be necessary to exclude the presence of appendical abscess or right adnexal disease or perinephritic abscess.

If there should be perforation into the mesentery of the terminal ileum, a small abscess may form in the mesentery. In other instances, in which a fistulous communication has been established between the diseased segment and other abdominal structures, such as the sigmoid, cecum, another loop of small intestine, the uterus, vagina, or bladder, there may be an extensive or a very large mass or practically none at all on examination. Ordinarily these fistulas may be discovered by the roentgenologist, the surgeon or by the pathologist after the surgeon has finished.

In regional ileitis and ileocolitis a hypochromic anemia often is present. The mild anemia is usually not due to loss of blood In the average patient the leukocyte count is within normal range

[illegible] In instances [illegible] excluded and [illegible]

The prognosis seems to depend solely on the extent and the *intension of the* disease, irrespective of the treatment. The intension of the disease is determined by the severity of symptoms and rapidity of development of the complications In those who have amebic infections and ileitis, the ileitis is not materially improved by getting rid of the amebae In the absence of pulmonary tuberculosis intestinal tuberculosis usually can be excluded. Among children and adolescents an occasional one will be found in whom an extensive tuberculous enteritis or enterocolitis cannot be distinguished roentgenologically from ileitis

The longer the interval after operation, the greater is the incidence of recurrence.

Solitary Primary Ulcers of the Jejunum or the Ileum. Simple solitary or primary benign ulcers, which closely resemble peptic ulcers, occasionally occur in the jejunum or the ileum. The jejunal ulcers are the commoner of these rare ulcerations.

Jejunal Ulcer. Primary jejunal ulcer occurs in the proximal portion of the jejunum. In appearance the ulcer resembles peptic ulcer. The size of [illegible]ion varies

up to 2 cm. in diameter. More than one ulcer may be present. Heterotopic gastric or pancreatic tissue is not often found in the ulceration.

The patients may have as the manifestations those of spontaneous perforation Some of these patients, in giving the history, complain of postprandial pain relieved by the ingestion of food or alkalies More often the history reveals periodic abdominal distress at irregular intervals The pain is situated in the lower part of the epigastrium, around the umbilicus

On examination there is mild epigastric and midabdominal tenderness.

Roentgenologic studies of the small intestine, after the patient has ingested a barium meal, may establish the diagnosis of solitary ulcer in the jejunum These ulcers may perforate or form strictures. If these complications occur, their presence is diagnosed by the surgeon

Ileal Ulcer. Primary ulcers of the ileum, as recorded by Brown, occur in the lower 3 feet (0 9 meter) of the ileum. Heterotopic tissue is not found in these ulcers These lesions may perforate, or bleed Bleeding and anemia were the outstanding features in more than one half of Brown's cases.

Nausea and vomiting, and pain situated in the lower part of the epigastrium, around the umbilicus, or in the lower right abdominal quadrant, are common. The pain, of a colicky type, is often referred to the back, and is not relieved by antacids. The ingestion of food may aggravate or relieve the pain or may have no effect on it. Apparently the foregoing symptoms are not severe, for the majority of patients seek relief for perforation and peritonitis, obstruction, melena, and anemia.

Results of the examination are often negative In some of these patients the spleen is palpable, and in some, aside from the enlarged spleen, distinctive physical findings are lacking.

Roentgenologic examination may be diagnostic. In others the ulcer is found on exploration for Meckel's diverticulum which is not present.

Tumors of the Small Intestine. Many of the lesions of the small intestine, such as small benign tumors, are discovered at necropsy as incidental findings which have not given symptoms

Benign Tumors of the Small Intestine. Benign tumors of the small intestine occur most frequently in the duodenum and the ileum In the order of the frequency of their occurrence the following benign tumors are listed. (1) adenomas and pancreatic rests which enlarge, these occur with equal frequency and together constitute by far the greatest number of the benign tumors; (2) myomas, adenomyomas, fibromyomas and osteochondromas, (3) lipomas, (4) angiomas and hemangiomas; (5) cysts and cystadenomas, all of which are of rare occurrence even in the over-all number of benign tumors

The *symptoms* of manifested tumors of the small intestine are rapid loss of weight, anemia and bleeding, or symptoms due to intermittent or total intestinal obstruction or intussusception

In the usual instance of a tumor of the small intestine the obstructive symptoms are of insidious onset In the beginning there is a mild colicky abdominal pain perhaps associated with slight distention and often with nausea and, at times, vomiting The insidious progressive type of intestinal obstruction is seen in cases of sarcoma, carcinoma, carcinoid tumor, lipoma, hemangioma and cysts. Tumors growing extraluminally may not give rise to obstruction until they have attained considerable size These large tumors cause a failure of the general health, often before a palpable mass is present and before obstruction occurs

Ulceration of a benign tumor may cause attacks of pain due to spasm and irritability of the intestine. In some instances the first complaint depends on the development of an abscess or a fistulous communication between the lumen of the intestine and the necrotic center of an extraluminal growth. A free perforation due to ulceration or necrosis is a rare first indication of tumor of the small intestine.

The general physical examination is negative in the absence of complications of benign tumors of the small intestine. When complications are present these may often be revealed by the findings on general examination.

Diagnosis is established by roentgenologic examination In some instances the diagnosis is not made until surgical exploration is done in order to determine the cause of the abdominal symptoms.

Malignant Tumors of the Small Intestine. *Carcinoma.* Malignant tumors of the small intestine are uncommon The average age of patients who have carcinoma of the small intestine is about 10 years less than the average age for patients who have gastric cancer. These tumors may occur before the age of 40 years. Two men are affected to each woman who has a carcinoma of the small intestine.

In the recorded experience of Pridgen, Mayo and Dockerty the adenocarcinoma occurs most frequently in the jejunum and decreases in the middle section of the small intestine with another increase in incidence in the ileum. The lesions are annular, ulcerative and polypoid in types. The annular type is the commonest. Proximal to the lesion the bowel often is dilated In extreme dilatation of the bowel perforation may ensue In instances of polypoid lesions intussusception may be present. Metastasis to the liver and cervical lymph nodes may be present

This rare disease is commoner in men than in women The greatest incidence of the disease is between 45 and 50 years of age Bleeding is the most important symptom of cancer of the mesenteric small intestine It may be manifested as occult blood in the stools, as an unaccountable hypochromic anemia, or as a massive hemorrhage producing large, tarry stools. Mechanical obstruction is responsible for the subjective complaints of many patients who have intestinal carcinoma. The symptoms in some patients who have intestinal obstruction are gradually progressive, beginning with intestinal colicky pain and slight nausea, followed by increasing abdominal distention, visible peristalsis, nausea, vomiting and constipation. The onset of symptoms in other patients who have intestinal obstruction may be abrupt when there is a rapidly developing mechanical obstruction Intussusception of a pedunculated carcinoma and, less frequently, the torsion or knuckling of a loop of bowel may be responsible for the acute obstruction. The onset in still other patients may be that of a localized peritonitis or a subacute perforating peptic ulcer

When the symptoms of carcinoma of the jejunum and of the ileum have become manifest, the roentgenologic demonstration of the lesion is usually easy.

Carcinoid Tumors Carcinoid tumors affect persons in the older age groups and may be responsible for disabling symptoms. They also may affect middle-aged persons

Carcinoid tumors tend to involve the terminal segments of the ileum as small, submucosal nodules with minimal ulceration. In half of 30 cases reported by Dockerty and Ashburn in which accurate information was available, the tumors were multicentric Infiltration was a pronounced feature as regards submucosa, muscularis, peritoneum, nerves, lymphatic spaces and blood vessels. Puckering and kinking in the region of tumor invasion provided a possible valuable roentgenologic sign of identification Involvement of regional nodes was observed in 11 cases and hepatic metastasis in 5 instances Evidence was afforded on the basis of microscopic studies that all carcinoid tumors are in essence peculiar, low-grade (grade 1, Broders) adenocarcinomas. In 13 of these 30 cases there was undoubted evidence of metastasis.

The symptoms may be indistinguishable from those of a carcinoma. The symptoms may be those of intestinal obstruction caused by a knuckle-shaped kink formed by a carcinoid in the bowel.

The roentgenologist may have suspected the correct diagnosis He usually reports an obstructing lesion. However, the diagnosis cannot be made except by histologic study of the tissue.

Sarcoma. Sarcomas are variously classified by the pathologists [illegible] leiomyo-

sarcoma, (2) fibrosarcoma, (3) angiosarcoma, (4) malignant lymphoma and (5) malignant melanoma.

In most respects sarcomas (leiomyosarcoma, fibrosarcoma and angiosarcoma) and carcinomas are similar from the standpoint of their clinical manifestations.

The malignant lymphomas among the sarcomas tend to occur oftener in younger persons than do carcinomas; this is true more of the localized forms which involve the colon than of the forms involving the rectum The clinical course of sarcoma in most cases is rapid, and the duration of symptoms from the onset until the patient is hospitalized is, on the average, shorter than for carcinoma.

Abdominal pain tends to occur earlier in sarcoma and perhaps is more severe than it is in carcinoma Bleeding is less frequent than it is in carcinoma. Obstructive features are also less prominent because of the tendency of sarcoma to dilate the lumen of the bowel.

On examination often there are present fever, emaciation, pallor and debility which have developed more rapidly in association with sarcoma than they do with carcinoma Masses are palpable more often and usually are larger and more extensive in patients who have sarcoma than in those who have carcinoma. In contrast to the condition when carcinoma is present, digital examination of the rectum in patients who have sarcoma often reveals an intact mucosa over the tumor.

Lymphoblastomas of the stomach and intestines are described in association with diseases of the hemic system (Chapter 12)

Melanoma. Melanoma is rarely if ever primary in the small intestine. Melanoma of the intestinal tract is ordinarily secondary to a cutaneous pigmented lesion or a melanoma of the retina or rectum Secondary growths may appear in the intestinal tract without evidence of metastasis elsewhere.

In a patient who has malignant melanoma, pigmentation of the anal orifice may be seen, resembling the appearance of external thrombotic hemorrhoids Very suggestive of a pigmented lesion is a blackish discharge which may be obtained on the examining finger.

In some cases of intestinal melanoma, years have elapsed between the removal of an external growth and the appearance of the intestinal tumor The possibility of intestinal melanoma is considered only if symptoms of intestinal obstruction or bleeding occur in a patient who has previously had a pigmented tumor removed from elsewhere in the body

Diagnosis of Tumors of the Small Intestine. In the diagnosis of tumors of the small intestine, malignant, as well as benign, tumors in the duodenum capable of causing symptoms are demonstrated by roentgenologic examination In the rest of the small intestine greater difficulties are encountered by the roentgenologist. If persistent bleeding or symptoms suggestive of partial obstruction are present, roentgenologic studies, if negative, should be repeated If the roentgenologic findings are consistently negative, the diagnosis may have to be postponed for the surgeon to make when he explores for the cause of the illness If intestinal obstruction is present or impending it is unsafe to put barium into the small intestine

THE VERMIFORM APPENDIX

Development of the Processus Vermiformis and the Ileocecal Valve (Incompetent Ileocecal Valve) The ascending colon begins slowly to elongate at about the middle of fetal life The cecal bulge grows, extending as a blind sac beyond its junction with the terminal ileum The extension of the cecum beyond this junction is at first a pointed, horn-shaped projection The distal end of this transitive projection extends rapidly f[illegible]
at this p[illegible]
its point[illegible]
pointing in that direction When the appendix is at the top of the cecum, these variations

in the size and shape of the cecum are differentiated by the roentgenologist from contractions of the cecum as the result of an inflammatory process.

Normally, during the lengthening process of the cecum, the cecal walls become thinned There is a diverticularization of the thinned walls, which flex and rotate medially and downward. These movements of flexion and rotation form the ileocecal valve. Whether or not the ileocecal valve is competent in adult life depends on completion of the processes of (1) dilatation, (2) flexion and (3) rotation. There cannot be a competent ileocecal valve in the presence of a fetal type of cecum

The appendix may be absent. It may be excessively long or short. It may be situated in any part of the abdomen in association with varying degrees of failure of rotation of the intestines In situs inversus viscerum it is on the left side of the abdomen

POSITION OF THE APPENDIX (PROCESSUS VERMIFORMIS). The position and direction of the normal appendix have been variously described and much discussed, owing to the fact that the appendix is so curled, curved, and twisted on itself that it is impossible to say that it points in any definite direction, and that, being so mobile, it may be found in almost any position, swinging around with its point of attachment to the cecum as the axis This point being its axis, the greatest displacements of the appendix in the abdomen depend on the situation of the cecum.

Diseases of the Appendix Due to Prenatal Influences. Congenital malformations of the appendix are rare and consist of complete absence, a double appendix, and so-called split appendix

Diverticula of the appendix may be single, but usually they are multiple. The commonest location is along the mesenteric border or in the distal half of the appendix Importance is attached to them for their presence in association with acute appendicitis since the thin wall of the diverticulum is less able to withstand infection and increased tension without rupture than is the normal appendical wall Their presence in association with pseudomyxoma peritonaei is not understood

Polyposis of the appendix may occur, but because of its rarity little is known concerning this condition In congenital disseminated polyposis of the colon the appendix is often free from polyps.

Appendicitis. Appendicitis is a bacterial infection which often seems to have been predisposed by local mechanical factors Heredity, diet, race, season, pregnancy, trauma and foreign bodies are unimportant etiologically. The sexes are affected equally. The disease occurs most commonly in adolescence and early adulthood but no person, regardless of age, may be exempt from an attack of appendicitis.

Irritation secondary to the presence of *Oxyuris vermicularis* or other intestinal parasites often has been recorded as a cause of appendicitis Like foreign bodies, parasites in the appendix may be of little significance A worm may simply like to live in the appendix

Acute appendicitis may occur during the course of acute viral or bacterial contagious diseases for instance, measles, mumps, varicella and scarlet fever. Appendical involvement may occur in association with rheumatic fever and periarteritis nodosa, not as a true acute appendicitis but as a rheumatic involvement or as a periarteritis of the vessels of the appendix. During the course of many an acute infection, for instance, pneumonia, symptoms of appendicitis may appear The signs and the symptoms of appendicitis may occur during the course of acute porphyria and during acute hemolytic crises, particularly in sickle cell anemia.

There are two sources of infection available to the appendix, (1) the enterogenous and (2) the hematogenous Acute appendicitis, in by far the greater number of cases, is of enterogenous origin Appendicitis due to hematogenous infections may occur during septicemia, go unobserved, and be found at postmortem examination.

It is now recognized that often the cause of abdominal symptoms identical with

those of appendicitis may be mesenteric adenitis from any cause However, it is well to know that mesenteric adenitis may accompany acute appendicitis.

PATHOLO [illegible]
(1) acute c [illegible]
abscess, (4) [illegible]

SYMPTO [illegible]
vomiting A [illegible]
midabdominal pain. Nausea and vomiting tend to subside as the pain becomes localized over the appendix The pain and its intensity constitute the most important symptom of acute appendicitis

Constipation is the commoner state of the bowels in adolescents and in adults. Diarrhea is commoner in young children

The temperature is rarely more than 100 F (37 8 C). It has been thought that the more severe the disease of the appendix, the higher will be the febrile reaction. The height of the fever is not a trustworthy guide to the severity of appendicitis. In the event of perforation of the appendix and local abscess formation, however, the temperature often reaches 101 F (38 3 C) The fever tends to be higher in children than in adults. In the aged, appendicitis may be present without fever.

Increase in the pulse rate has some relation to the rise in temperature. The pulse rate rarely exceeds 100 beats per minute unless gangrene or perforation of the appendix has occurred. In adults, when the pulse rate exceeds 110, perforation of the appendix should be suspected and is usually found to be present.

The cessation of localized abdominal pain which previously had been severe usually signifies a termination of the acute process, gangrene or perforation is likely to be present when the pain subsides quickly, especially if the pulse rate does not decrease and the temperature does not subside.

EXAMINATION. There is tenderness in the right lower abdominal quadrant at McBurney's point, which is situated approximately just below the junction of the middle and outer thirds of a line drawn between the anterior spine of the iliac crest and the umbilicus The region of maximal tenderness varies according to the situation of the appendix in the abdomen In failures of intestinal rotation and fixation of the intestines, the point of tenderness may be situated almost anywhere in the abdomen. When the appendix is low in the right side of the abdomen, the pain may be lower in the abdomen, or in the right flank or the back In a pelvic appendix the point can best be palpated on rectal or vaginal examination When peritoneal irritation is widespread the tenderness becomes more diffuse, and accurate localization is not possible. Innate rigidity of the abdominal muscles, which often is present in ticklish and in neurotic individuals, or the lack of co-operation of the patient adds an uncontrollable hazard to localization of tenderness

Various physical signs which are often manifested in some of those who have appendicitis have been described as indicating degrees of infection or differential diagnostic points These signs are of no great diagnostic value and they would be detected and correctly interpreted even if their names were unknown

1 Irritation of the parietal peritoneum by the inflamed appendix permits *rebound tenderness* to be elicited To test for rebound tenderness a steady, firm pressure is applied over the region of tenderness When the pressure has been firmly applied, the examiner's hand is suddenly removed The patient then evinces the sharp pain thus induced When muscle guarding is present, rebound tenderness cannot be elicited This test is seldom necessary It is punishment to those who have appendicitis

2 Rigidity of the abdominal wall, or *muscle guarding,* may be detected by applying firm pressure with the palm of the hand When present and not due to nervous factors, it is a sign of peritoneal irritation It is usually limited to the quadrant or region in which the disease is situated

3 Hyperesthesia of the skin overlying an acutely diseased appendix or any other acutely inflamed viscus is usually present This finding is of value in diagnosis if sufficient

time is spent to be sure of the presence of the hyperesthesia and the examiner is well enough experienced to interpret the vagaries of overlapping cutaneous nerve innervations.

4 *The prone test for diagnosis of retrocecal appendicitis* consists in palpating the abdomen with the patient lying face downward. If acute retrocecal appendicitis is present, gentle palpation of the right lower quadrant of the abdomen with the patient prone will elicit greatly increased tenderness, serving to differentiate the appendicitis from pelvic and renal lesions Too much dependence should not be placed on this test because the results are often positive in colitis and ileitis.

When the appendix is retrocecal, as it often is, the pain may be more intense in the right flank or right renal region

Always included in descriptions of the physical findings in acute appendicitis, but of rare occurrence, are (1) an acutely inflamed appendix producing irritation of the psoas muscle and giving rise to pain on the anterior and inner aspects of the right thigh; (2) an acutely inflamed appendix resting on the ureter and giving extension of pain into the bladder or scrotum, dysuria and desire for frequent micturition, (3) an inflamed appendix situated low in the pelvis, causing pain lower down in the abdomen and in the left lower part of the abdomen, and (4) an inflamed appendix in contact with the sigmoid or the rectum and sometimes producing desire to defecate, painful defecation, or pain extending to the back of the pelvis or to the perineum.

Always too it is emphasized to elicit the knee reflexes lest a tabetic crisis be called appendicitis and operation be advised

On rectal examination of one half of the patients who have acute appendicitis, tenderness may be elicited high in the right side of the pelvis. The rectal examination is particularly valuable in children, in whom the relatively shallow pelvis permits a much higher level to be reached than is possible in the rectal examination of adults Bilateral tenderness from acute appendicitis is rare, and when present it often indicates a pelvic abscess or pelvic peritonitis from appendicitis or salpingitis.

Urinalysis is a routine procedure before any definite conclusions are made in regard to the presence or absence of appendicitis The results are usually negative in appendicitis An occasional erythrocyte in the urine is not significant Definite hematuria indicates urogenital disease, usually a calculus of the kidney, ureter, or bladder It is true that on rare occasions an inflamed appendix involves the ureter, but this is so exceedingly uncommon that a hematuria must be considered to arise from urogenital disease, hypothetic assumptions should not be made to justify the diagnosis of appendicitis Pyuria likewise is infrequent in acute appendicitis, but if the patient is a female, an aged man or a child and pyuria is present, a catheterized specimen should be examined to exclude contamination of the urine If the urine appears pink or if the patient appears to be jaundiced a hemolytic crisis is suspected.

A normal total leukocyte count may be present even in patients who have severe appendicitis The leukocyte count is a most valuable laboratory procedure when used repeatedly while a patient is under observation for appendicitis If the trend of a series of leukocyte counts is upward, this trend is significant of an advancing infection and thus may be helpful in making a diagnosis In children the leukocyte count averages 2,000 cells per cubic millimeter of blood higher than in adults during the same phase of the disease Usually there is a high percentage of neutrophils present. When the number of leukocytes exceeds 20,000 per cubic millimeter of blood, unless peritonitis is present serious consideration should be given to diseases other than appendicitis, particularly to lobar pneumonia in the basilar lobe of the right lung.

Diagnosis of Acute Appendicitis. Epigastric or midabdominal pain, preceded or followed by nausea and vomiting, with the pain tending to localize after an hour or so in the right lower quadrant, generally is appendicitis if the appendix has not been removed, or if the patient is not a colored man with sickle cell anemia, and it is good judgment to consider it so. Anorexia is always associated with the pain. When the pain localizes in the lower right abdominal quadrant, it tends to

become constant. The intensity of the symptoms increases until the appendix ruptures or until the attack spontaneously subsides

The differential diagnosis of acute appendicitis may require a consideration of all the acute conditions which occur in the abdomen In women of the childbearing age, diseases of the genital organs are of immediate differential diagnostic importance. These diseases may be enumerated acute salpingitis, rupture of a graafian follicle (mittelschmerz), torsion of an ovarian cyst, a pedunculated fibroid of the uterus, a cyst of the hydatid of Morgagni, an ovary with a long mesenteric attachment or a ruptured ectopic pregnancy Likewise diseases of the urinary organs, namely, ureteral calculus, pyelitis of the right kidney, and intermittent hydronephrosis of the right kidney are to be considered Finally the blood dyscrasias prone to be complicated by hemolytic crises, especially sickle cell anemia, must be considered

The prognosis in cases of acute appendicitis is largely dependent on the complications

Immediate surgical operation is indicated for an acute appendical inflammation which seems to be progressing An interval of delay in operating is indicated for a subsiding acute or recurring subacute appendicitis, and for the localized abscess.

The mortality rates given by different statistical studies range so widely that they are hardly worthy of recording The surgical mortality rate in uncomplicated appendicitis is from 1 to 2 per cent

Acute Appendicitis in the Aged An elderly patient who has an acute appendicitis may not appear seriously ill even during the early stage of peritonitis There are digestive symptoms attributed to dietary indiscretions. Anorexia, nausea and vomiting may be present Abdominal pain is not severe and tends not to localize Often there is little or no fever Many of these patients are not seen until peritonitis has developed Gangrene, perforation and peritonitis develop rapidly Due to the advanced stage of the appendicitis when the patient is first examined it can easily be confused with intestinal obstruction, and time may be lost in attempts to locate a growth.

On physical examination slight or moderate distention of the abdomen with little or no tenderness will be observed Commonly laboratory data are unreliable either for diagnosis or as a measure of the severity of the disease

The diagnosis cannot be made unless there is some localization of pain and tenderness over the appendical region accompanied by a moderate leukocytosis.

Acute Appendicitis in Children In a child an acute infection of the upper part of the respiratory tract often precedes appendicitis In contrast to the symptoms *in adults, diarrhea may be present*

[illegible]

the [illegible]

be a [illegible]

left alone. Even in the presence of generalized peritonitis the abdomen, although distended, may be soft and tenderness may be slight.

The diagnosis of appendicitis in children is more dependent on the rectal examination than in adults, since in children a much greater part of the abdomen is within reach of the palpating finger The laboratory findings of blood counts and, in some cases, of a bacteriologic study of the peritoneal fluid are valuable diagnostic assets

[illegible]

acute appendicitis in children are acute hip disease, osteomyelitis of the femur and ilium, psoas abscess, inguinal or femoral lymphadenitis, gastroenteritis, intussusception, and inflammation of Meckel's diverticulum

COMPLICATIONS OF ACUTE APPENDICITIS. The signs of abscess in the early stages of its formation are not definite because there is present no localization of findings, and it must be decided whether the appendix is ruptured or not. If the process is localizing, a rectal examination will sometimes enable the examiner to palpate this localizing process A decrease in the temperature and a lessening in the degree of leukocytosis may indicate localization. Usually fully formed appendical abscesses cannot be diagnosed if they are not in the usual places. The unusual situations for appendical abscesses are retrocecal or subhepatic. In these situations a preoperative diagnosis is impossible.

Hepatic abscesses, although *rare, are serious complications of appendical abscesses* One third of all perihepatic and subphrenic abscesses are caused by a ruptured appendix

Formation of fistula and sinus may eventually occur when an abscess forms. *Inclusion in the wall* of an appendical abscess of part of a hollow viscus, such as the cecum, urinary bladder, sigmoid, or rectum, may result in rupture of the abscess into that organ with fistulization

When acute appendicitis is complicated by adhesions, formation of abscess, or peritonitis, intestinal obstruction and paralytic ileus are common.

Extension of infection from the appendix may result in thrombophlebitis of the iliac or femoral veins, from which may be released an embolus which lodges in the lungs. If the embolus is large, death quickly ensues. Emboli may form in these veins during the course of appendicitis without detectable extensions of the infection.

CHRONIC APPENDICITIS. RECURRING APPENDICITIS. There is no agreement as to what should be considered chronic appendicitis Such a condition no doubt exists, but it cannot be diagnosed. Recurring appendicitis is simply repeated attacks of acute appendicitis

Mucocele of the Appendix. Mucocele of the appendix has been known also as colloid or pseudomucinous cyst, hydrops mucinous cyst, myxocele and pseudomyxoma of the appendix. Mucoceles vary in shape and size. Their contents consist of a mucoid material which may be thick or thin but ordinarily is viscous, stringy and tenacious.

A mucocele of the appendix forms when there is obstruction of the lumen of the *appendix, and the contents of the lumen remain sterile.* The continued secretion of the mucosa of an appendical stump, inverted at the time of surgical removal of the appendix, is a common cause of the formation of mucocele.

Most mucoceles are discovered and removed during an operation performed because of some other disease. The roentgenologist often diagnoses mucocele. Only rarely do mucoceles become large enough to be palpated through the abdominal wall, and then the diagnosis of tumor in the right lower abdominal quadrant is usually made Surgical removal is the only treatment.

Carcinoid (Argentaffine) Tumors of the Appendix. The cytoplasmic granules of the chromaffin cells of the intestine are capable of reducing silver compounds to brown-black particles, and this reaction accounts for the name argentaffine tumors, for these tumors arise from argentaffine cells. These cells are more numerous *in the appendix and the terminal portion of the ileum* than in any other part of the intestine.

Carcinoid tumors of the appendix occur in both sexes, in patients of various ages from childhood to senility, inclusive They are found most frequently in adults less than 35 years of age.

Carcinoids are found in all situations, ranging from the cardio-esophageal junction to the rect[illegible] result of chronic inflammatory processes. [illegible] m, where the incidence of origin [illegible]

Regardless of size, point of origin, or presence or absence of metastasis, carcinoids

possess essentially the same microscopic features of cytologic differentiation and histologic architecture. Origin from, and differentiation into, glandlike structures is a constant observation. All these tumors are of grade 1 malignancy (Broders).

Appendical argentaffine tumors usually are discovered at the time of appendectomy. Rarely do these tumors metastasize. Carcinoid tumors of the ileum involve only a part of the lumen. They cause intestinal obstruction and they may metastasize to local lymph nodes.

The prognosis following complete removal of these growths is usually good. However, these tumors are not benign

THE COLON

The colon performs no important digestive functions. The colon absorbs water and electrolytes from the intestinal chyme passed along to it from the ileum. When the body is deprived of the colon the kidneys immediately assume this function. The other function of the colon is one of convenience storage of the dejecta to be evacuated at some convenient time which is dictated by custom and habit

The large intestine comprises (1) the cecum and appendix, (2) ascending colon, (3) transverse colon, (4) descending colon, (5) sigmoid flexure, composed of the iliac colon and pelvic colon and (6) the rectum and anal canal

The length of the large intestine exclusive of the rectum and anal canal is 4 feet 6 inches (137 cm) in the female, and 4 feet 8 inches (142 cm) in the male

The position of the colon cannot be accurately predicted

Size of the bowel is an undependable criterion in distinguishing the large intestine. There are three longitudinal bands (taeniae coli) on the colon, from 1/4 to 1/2 inch (6 to 13 mm) wide, according to the amount of distention.

The sacculations of the colon are produced by the longitudinal bands being one-sixth shorter than the rest of the tube Although sacculation tends to become less marked on distention, it is still a valuable means of identification. Dividing the longitudinal bands will cause the sacculation to disappear and the gut to lengthen Diverticula of the colon are common after the age of 40 years

Appendices epiploicae, or the small tags of peritoneum containing fat, are found along the large intestine as far as the rectum They are most numerous along the inner longitudinal band and the transverse colon These are often the site of diverticula and thus diverticulitis or appendicitis epiploicae.

Often the cecum and the descending and sigmoid colons are normally palpable. The colon cannot be outlined by percussion

Diseases of the Colon Due to Prenatal Influences. *Primary Megacolon.* This disease is known also as Hirschsprung's disease, idiopathic dilatation of the colon, and congenital dilatation of the colon

[illegible] or of

[illegible] The

The name Hirschsprung's disease has been used to designate extreme dilatation of the colon of congenital origin occurring in infants and young children, primary megacolon with the same clinical and morphologic features is seen in adults. It is not known whether or not all instances of the condition among adult persons are due to a primary congenital defect

Swenson and his associates have contended that the primary lesion in megacolon is in the distal, nondilated segment Despite this contention, grossly this portion of the colon or rectum appears normal They demonstrated to their satisfaction that, in control patients, groups of strong peristaltic waves progress from the transverse colon to the anus. The authors have expressed the belief that the absence of normal propulsive waves in the rectum and rectosigmoid constitutes a physiologic defect that results in chronic obstruction

Among the neurogenic causes there is an absence of parasympathetic ganglion cells in the distal strictured segment of the colon

Grossly, the involved segment of bowel is dilated and elongated and its walls are thickened The sigmoid colon is the segment commonly affected. In some of the more advanced instances the whole colon is involved, the dilatation of the intestine ending abruptly at the ileocecal junction. Usually the mesentery of the sigmoid is greatly elongated and thickened Chronic inflammatory changes are frequent and may be manifested by hyperplasia, necrosis of the surface membrane from fecal pressure, and actual stercoral ulcerations

Primary or idiopathic megacolon has been reported in persons of all ages from birth to 80 years. Familial incidences have been observed. Boys and men are more *commonly affected than girls and women*

SYMPTOMS Megacolon may not produce severe symptoms in the older child or adult and may be discovered accidentally by roentgenologic examination of the colon made because of some other condition. The two constant symptoms are obstinate constipation and enlargement of the abdomen.

The constipation, dating from birth, may be the chief and only complaint Many days, weeks, or even months may elapse without a bowel movement, and without local or systemic symptoms attributable to the long period of intestinal inactivity. In instances of milder megacolon, bowel movements occur at irregular intervals, causing no inconvenience The stools, when they do occur, vary greatly in consistency and in size and shape Large globular masses are often passed. Cathartics and enemas have little effect Intermittent intestinal obstruction is present from time to time There may be frequent small rectal discharges unassociated with symptomatic relief and accompanied often by tenesmus and frequent desire to defecate

Abdominal pain is rarely severe in the absence of a complication such as volvulus or peritonitis The chronic character of the distention probably accounts for the relative lack of subjective complaints.

In instances of severe long-standing megacolon, symptoms indicative of loss of weight, asthenia, and prostration occur. Fever is not present unless there is secondary infection, pneumonia, volvulus, or complete intestinal obstruction

In

infa

diar

spaces are widened and the subcostal angle is obtuse. The lateral walls of the thorax bulge. Distention of the skin causes atrophic changes. The skin is shiny, glazed and dry The superficial veins are visible Edema of the feet and legs which often is present may be caused by the pressure of feces and gas in the colon.

Peristaltic movement may be seen Fecal masses may be palpated in the abdomen or during the bimanual examination of the rectum, or they may be detected only by ballottement during the examination.

On percussion the abdomen is uniformly tympanitic Hepatic dullness is absent or diminished. The tympany extends to, and often includes, the lower part of the left side of the thorax, anteriorly, laterally and posteriorly There is no evidence of shifting dullness, because ascites does not accompany megacolon

In some children and often in adults there are no signs on physical examination and the condition is found during the routine sigmoidoscopic examination in search for the cause of the constipation.

DIAGNOSIS. A diagnosis of megacolon is established by sigmoidoscopic examination or by roentgenography after a barium enema A differentiation of congenital ... of the anal

... ive the first

In the absence of complications the prognosis for patients ... 4 or 5 years of life is fairly good Megacolon occurring in older children and in adults seems to have little effect on life expectancy. In most patients a colonic regimen can be employed which permits of health. If health cannot be maintained

on such a program, resection of the involved segment of the colon or of the entire colon should be recommended.

Acute Infections of the Colon. ***Shigella and Shigellosis (Bacillary Dysentery).*** Organisms of the genus *Shigella*, family Enterobacteriaceae, are the etiologic agents of bacillary dysentery. Some species occupy doubtful positions, while still others are nonpathogenic for man

All species of *Shigella* tend to be antigenically heterogeneous Serologic overlapping between species is common. Antigens present in certain species of *Shigella* have been detected in other enteric bacilli. Despite these irregularities in antigenic structure, classification of *Shigella* depends on serological results

The *Shigella dysenteriae* and *Shigella ambigua* are antigenically homogeneous These organisms cause a severe dysentery. The para-Shiga group comprises three main subdivisions, namely, (1) Flexner's bacillus, (2) Hiss and Russell's "Y" bacillus and (3) Strong's bacillus These are antigenically heterogeneous, and at least five types have been recognized. These types are referred to as paradysenteriae V, W, X, Y and Z. The *Shigella sonnei* is heterogeneous and two antigenic types are recognized. These organisms are nonpathogenic. Four types of *Shigella dispar* have been distinguished The antigenic structure of *Shigella alkalescens* is complex These organisms contain at least five antigenic components A, B, C, D and E A is species specific, B, D and E are coliform and paracoliform bacilli, while C is found in *Shigella paradysenteriae* as well as in *Shigella alkalescens*. These organisms are nonpathogenic in man

The National Institutes of Health has maintained a field laboratory for the investigation of the acute diarrheal diseases A total of 8,643 survey fecal cultures was obtained on representative persons Institutional inmates, among whom clinical disease and subclinical infection were relatively common, have been studied, using new, highly selective culture mediums which increase the reliability of bacteriologic findings

The proportion of adult patients who have endemic diarrheal disease whose stools were found culturally positive for *Shigella* by The National Institutes of Health was 76 per cent of those who had severe disease and 58 per cent of those who had milder disease There was an increase in the proportion of those with positive fecal cultures as the number of examinations during illness increased The percentage with positive findings was lowest for the group whose ages were less than 6 months, but the percentage varied widely with area and with severity of illness. The cultural findings for institutional inmates were similar

This study by The National Institutes of Health seems to indicate that the cause of diarrheal disease varies with area, with season and with age of persons concerned.

The *Shigella paradysenteriae* infections vary in incidence and occur more frequently than is usually thought, especially in the younger age groups These infections seem to be more frequent in infants less than 2 years old than in older patients. The rate declines thereafter, with fewer instances among adolescents and adults.

Among the general population the cases occur chiefly during the summer and early autumn There is a pronounced concentration of incidence among the poor

convalescents are carriers The average duration of the convalescent carrier state in 50 per cent of the cases is one month In some instances the carrier states may last a year Chronic carriers, if there are any, are exceedingly rare The passive carrier state is unusual at ages of less than 1 year but increases in frequency with age More than one half of the children infected at 3 years and most of the infected older children and adults are passive carriers It is therefore not surprising that diarrheal diseases commonly appear sporadically The mode of spread is mainly by a direct or an indirect person-to-person distribution of the infecting organisms.

Often there is no evidence which suggests that the etiologic agents responsible

for the diarrheal disease are brought into the household in water, milk or any other food product. The disease and flies are often found in the same environment, but there is no good evidence that flies are important in the dissemination of *Shigella*.

PATHOLOGY. The pathologic changes of bacillary dysentery are limited to the colon and the terminal ileum The first changes are observed through the sigmoidoscope and consist of transverse red swollen ridges. The mucosa is red and presents small diffuse scattered hemorrhagic areas interspersed with purpuric spots beneath the mucosa The inflammation involves the mucosal glands, the mucosa swells and thus a granular appearance is imparted. In the acute severe instances of the disease the entire mucous surface may become necrotic and a membrane forms. During healing or after the acute process has healed, retention cysts in the mucosa may be formed and may remain for several weeks or a month or more. From the fluid of these retention cysts may be cultured the dysentery organisms These cysts are the means of the production of carriers

During the acute stages there is cloudy swelling of the liver, kidneys, and heart as the result of the fever The mesenteric lymph nodes of the colon are swollen and soft Splenic enlargement may be present and there may be focal necrosis Organisms of the genus *Shigella* rarely if ever produce a septicemia. They remain limited to the colon and the lower segment of the small intestine.

SYMPTOMS The incubation period of bacillary dysentery may be as short as a half a day or as long as 7 days, the average being 2 days. The acute phase of the disease is self-limited to about 12 to 14 days.

There are variations in the number of bowel movements from a few loose stools daily to continuous tenesmus and involuntary passage of liquid feces. The most common and clinically the most important form of the disease is that manifested by a mild diarrhea The onset may be so insidious that it is difficult to determine accurately when the illness began

In the moderately severe forms of the disease the onset is often abrupt with colicky abdominal pains and diarrhea with or without fever. The abdominal pains and tenesmus steadily increase. The dejecta from the bowels contain mucus and blood. The discharge of blood and mucus often is not excessive and grossly may not be detectable Dysuria may be severe and, if so, diagnostically confusing Likewise severe abdominal pain may arouse suspicion that appendicitis or gallbladder disease is present.

Bacillary dysentery may commence with severe colicky abdominal pain and vomiting which are followed shortly by diarrhea and tenesmus Stools vary in number from 10 to 60 per day. The stools at first contain some fecal material, but within 24 hours they will consist of clear, tenacious, viscid mucus streaked with blood. Fever may vary widely, being remittent or constant. It sometimes rises to 104 F (40 C). In some of the seriously ill patients the prostration is so severe that no rise in temperature occurs. In the critically ill the temperature is subnormal. The dehydration, continued desire to defecate, and straining of tenesmus completely exhaust the patient. These symptoms tend to subside when hydration is accomplished by parenteral administration of fluids

Relapsing forms occur. Exacerbations return with great regularity but with symptoms less severe than the original ones. The effects on body nutrition of several relapses may be disastrous

EXAMINATION. The findings on physical examination depend on whether the disease is mild without physical findings or severe with dehydration, mental confusion, increased pulse rate and low blood pressure Generalized abdominal tenderness and definite muscle guarding are present in severe bacillary dysentery.

In the acute stage of bacillary dysentery, roentgenologic examination is impos- ... medium.

any

findings that can be distinguished from those present in chronic nonspecific ulcerative colitis

The sigmoidoscopic findings are not definitely diagnostic of the type of dysentery present. In all types of bacillary dysentery there are red, swollen transverse ridges. The mucosa is reddened and there are present diffuse scattered hemorrhagic areas interspersed with small purpuric lesions beneath the mucosa When the process is fully developed the mucosal glands are involved and then the swollen mucosa may become granular in appearance In severe infection the entire mucous surface may become necrotic.

Material for culture is best obtained from swabbing the rectal lesions at the time of the endoscopic examination.

The leukocyte count varies from normal limits to 50,000 cells per cubic millimeter; usually there is a high percentage of neutrophils Erythrocyte counts vary; they may be high when dehydration is present and low when a mild secondary anemia exists in association with the chronic forms of dysentery.

The feces are examined for ova and parasites with particular reference to the presence of *Endamoeba histolytica*

DIAGNOSIS. The diagnosis of a particular etiologic agent as the cause of endemic acute diarrheal diseases can be made with certainty only in the laboratory by isolation of the etiologic agent or agents Cultures of the feces or material obtained by swabbing at the time of endoscopic examination are made After cultures are taken, chemotherapeutic or antibiotic agents should be given promptly. The physician knows that most of the patients suffering from acute diarrhea who come for attention have specific enteric infection due to some of the *Shigella* organisms The organisms which prevail in the United States rarely give rise to the severe bacillary dysentery usually described as endemic and epidemic in tropical climates.

Acute diarrhea caused by *Salmonella* cannot be differentiated clinically from that due to *Shigella* The former tends to give more fever, vomiting, greater abdominal tenderness and less blood in the stools A certain diagnosis must await laboratory findings (see *Salmonella* and salmonellosis, Chapter 17).

The features of an outbreak of an epidemic of dysentery are of diagnostic importance A sudden outbreak of severe dysentery is observed in staphylococcal food poisoning and in so-called sewage poisoning. Infections with enteric pathogens also occur as sudden outbreaks

Epidemics due to the *Shigella* continue throughout a period of several weeks The number of those ill with disease slowly or rapidly increases depending on the source from which the epidemic is disseminated and the sanitary control. The peak in incidence may be reached only after a month or more The decline in the number who succumb to the infection may be more rapid than the rise. An occasional instance of *Shigella* infection is observed for prolonged periods after an epidemic owing to convalescent and passive carriers infecting those about them Shigellosis is not attended by a septicemia

An epidemic of *Salmonella* infection begins in a period of 3 to 7 days, with a peak on the second or the third day

Highly selective mediums which permit growth of the enteric pathogens but inhibit growth of most of the nonpathogens are now available. Fecal specimens obtained by rectal swabs may be used for immediate direct inoculation of the selective mediums

Agglutination tests with the patient's serum cannot be interpreted with sufficient accuracy and speed to warrant the use of this procedure in diagnosing diarrheal diseases.

Acute Enterocolitis of Viral Origin. An acute diarrhea is a common manifestation of many systemic infections, bacteremia, septicemia or pyemia (see Chapter 17).

The acute enteritis due to bacteria or viruses may be divided into two large categories. (1) those due to an involvement of the stomach and intestines or intestines alone and (2) those which are part of a general infection or other systemic disease. In the second category the stomach and intestines or the intestines alone are affected secondarily.

The ingestion of partially decomposed, fermented, or putrefied foods accounts for many small epidemics of acute enteritis. The common agents which may give rise to infection from spoiled foods are the staphylococci, colon bacilli, *Clostridium botulinum*, and *Salmonella* which are not filtrable viruses

A disease of viral origin occurred in epidemic proportions in Philadelphia. The disease resembled the acute viral infection, white scours, which occurs in calves. This viral infection was characterized by diarrhea, nausea and vomiting. Results of bacteriologic examinations of the stools and pharyngeal secretions made by Reimann and his associates were negative. These investigators then resorted to experimentation on volunteers Broth garglings and suspensions of diarrheal stools were passed through a Mandler filter The resulting filtrates were nebulized. Twenty-one volunteers inhaled the nebulized stool filtrates In 11 of them diarrheal symptoms developed after an incubation period of less than 4 days. In 3 of the volunteers the diarrhea was accompanied by a mild nasopharyngitis Thirty-two volunteers inhaled nebulized filtered garglings; in 17 the diarrhea developed without nasopharyngitis. In 53 per cent of the volunteers who inhaled, typical viral diarrhea developed, as compared with only 9 per cent of the nonvolunteers, who acquired the disease during the same period of time from environmental exposure

Proved instances of dysentery due to viral origin as occurred in Philadelphia are lacking Influenza may cause abdominal cramps, diarrhea, nausea and vomiting. In contrast to the paucity of data, it is generally believed by many if not all physicians that viruses are potent influences for the initiation of intestinal disorders with dysenteric manifestations Indeed, many diseases which cause inflammatory changes in the stomach and intestines have their inception with acute diarrhea Often a patient who has any one of the following conditions. enteric tuberculosis, cholera, pyemia, septicemia, bacillary dysentery, a deficiency state, hypoproteinemia and severe anemia, congestive heart failure, hyperthyroidism, portal hypertension, chronic pulmonary disease, chronic intestinal obstruction, or embolic phenomena such as occur in rheumatic fever and bacterial endocarditis, or a patient in the terminal stage of nephritis (uremic states), or one who has malignant disease, or ulcerative colitis or terminal ileitis, will complain of having had a "virus dysentery" which started all of the trouble. It is well to know that the initial presence of an enteric virus is not necessary for the inception of any of these diseases If this fact is remembered, fewer diagnoses of viral dysentery will be made

Lymphopathia Venereum of the Rectum. This viral disease occurs in both men and in women. The adenopathies or buboes are the commonest manifestation of the infection in men The genito-anorectal form and rectal localization of the disease are much more frequently present in women than in men (see Chapter 7). The influence of race and color is not yet established, but the disease seems to be more frequent in the colored races than in whites.

The pathologic changes which lead to a rectal stricture are the important pathologic considerations here. According to Martin the perirectal and pararectal lymphangitis with marked lymphocytic infiltration finally becomes organized into dense fibrous tissue which produces stricture There is a great deal of connective tissue proliferation that seems to invade the muscular coats from the perirectal tissues.

It is the consensus that in women the rectovaginal and anorectal lymph channels are first affected and that then the perirectal lymph nodes also become inflamed and swollen Later, lymphatic occlusion and abscess formation ensue. This process is followed by ulceration, elephantiasis and fistulization The end result is scarring with rectal deformity and strictures

In some of those who have the disease there may be observed regional edema and

infiltration of the lymphatic structure of the dorsum of the penis which, when present with signs of other venereal infections, are pathognomonic of the coexistence of lymphopathia venereum.

After an incubation period of from 3 to 5 days there appears on the genitalia or in the orifices thereof a small herpetiform ulcer, papule, vesicle, or pustule (see Chapter 7).

Symptoms of rectal strictures develop without the patient having knowledge of any preceding manifestations. Because the rectal symptoms develop months or years after the buboes, and the course of the disease is so chronic, the stricture formation is probably a late phase of the infection

Rectal bleeding recurs daily for months or even years but rarely is the bleeding excessive. Little or no pain is experienced until the stricture develops. Mucoid seròpurulent or sanguinopurulent rectal discharge, watery diarrhea, and loss of appetite and of body weight are frequent complaints.

On examination the primary lesion of lymphopathia venereum is observed as a superficial ulceration on the external genitalia which may disappear soon or become a large, deep and extending ulceration If the ulcer forms on the upper two thirds of the vulva, inguinal or femoral lymphadenitis ensues There may be only one lymph node in the inguinal region enlarged with smaller nodes around it The enlarged node is tender Some time later a focal necrosis may occur and a small abscess follows. An extension of the necrosis to the surrounding superficial structures is manifested by ulceration and fistulization with fibrotic scarring

Skin eruptions associated with lymphopathia venereum were present in one third of Sonck's 400 cases The reaction is produced by sunlight, or by a hot steam bath. The primary lesion is a disseminated, punctate, reddish papular eruption appearing from one-half hour to 3 hours after exposure It is limited to the regions exposed to the sun's rays or to heat Desensitization occurs during spring or summer; however, the condition may last for 10 years

Sonck observed *allergic phenomena*, such as inflammation of the joints and eyes, erythema nodosum and rashes similar to erythema multiforme in association with lymphopathia venereum

There may be *ocular* manifestations of the disease Conjunctivitis may occur as a part of the infection of lymphopathia venereum. In the more severe infections abnormal visibility and tortuosity of the corneal nerves, increased opalescence of the cornea, blurred outline of the optic papilla, retinal edema, abnormal dilatation, tortuosity and a dark hue of the veins, ocular hypotension and retinal arterial hypertension are noted

On routine sigmoidoscopic examination when the infection is acute the mucosa of the rectum and the rectosigmoid is congested and bleeding, and the ecchymotic rectal mucosa is covered with blood clots and mucus In some patients there may be present macular, papular and vesicular lesions. The vesicular lesions contain yellow purulent contents These frequently ulcerate

In patients in the more chronic stage of the disease often no change is found except that of scarring of the mucosa in association with a smooth rectal stricture in the scar In other cases the proctologist may report that in association with the stricture the mucosa, both proximal and distal to the stricture, is reddened, edematous, granular, friable, bleeding, or thickened

The rectal stricture present late in the course of the disease tends to involve the rectal and the perirectal tissues extensively. The stricture is above the anorectal line, extending upward from about ½ inch to 4 inches (1.3 to 10 2 cm.). The caliber may admit the index finger, but is usually smaller. Vaginal examination may reveal the dense rectum The entire pelvis below the reflection of the pelvic peritoneum may be filled with dense indurated scar tissue

In instances of chronic infections there are emaciation, ocular changes, and

solar dermal eruptions. Conjunctivitis and allergic phenomena, such as erythema nodosum or rashes similar to erythema exudativum multiforme, are more rarely observed in the chronic forms of lymphopathia venereum. Edema, local or dependent, or both, may be present.

The diagnosis is made from the history, the physical examination and the positive reaction to the Frei test (see Chapter 7). Lymphopathia venereum is differentiated from factitial proctitis due to previous irradiation. It is separated from an ulcerative colitis by the history and by manifestations of the disease If strictures have resulted from trauma or physical agents, such as hot enemas, the history will differentiate

It is surprising that the opening in a strictured rectum, although extremely small, is capable of carrying on fair bowel function often for many years.

Diseases of the Colon Due to Higher Animal Parasites. The Class Sarcodina. This class, comprising unicellular animals that form pseudopodia, includes several orders and many families Most of the parasitic species in man are included in the order Amoebida and the family Endamoebidae.

The Parasitic Amebae of Man. At least 4 genera and 6 species of amebae of the family Endamoebidae live in man. These are· genus *Dientamoeba*, species *Dientamoeba fragilis*, genus *Endamoeba*, species *Endamoeba coli*, species *Endamoeba gingivalis*, and species *Endamoeba histolytica*, genus *Endolimax*, species *Endolimax nana*, and genus *Iodamoeba*, species *Iodamoeba buetschlii* However, *Endamoeba histolytica* is the only known pathogen in man.

Immunity The resistance of the host is the chief factor in determining the occurrence of clinical disease in amebic infections. However, strains of *Endamoeba histolytica* vary in virulence. Evidence of racial immunity is inconclusive, although the white races in the tropics seem more susceptible to clinical disease than the natives Continued exposure to heavy infections may overcome resistance. The relation of the carrier state to immunity is not clearly defined. Precipitins and complement-fixing antibodies have been demonstrated in the blood

Incidence Surveys which have been made to determine the prevalence of parasitic amebae in man have shown that the incidence of infection of these amebae is highest in the tropics and subtropics Thus the incidence, to a large measure, depends on geographic location.

Surveys for the incidence of amebic infection are not made in districts where these infections are not common It is therefore appropriate to say that in some districts of the United States of America amebae are common, and in others, rare

1. *Endamoeba histolytica.* Some authorities prefer the generic name *Entamoeba* to the approved *Endamoeba* Confusion in nomenclature has produced many synonyms. Among the more prominent are *Amoeba coli*, *Entamoeba dysenteriae*, *Entamoeba histolytica*, *Entamoeba tetragena*, *Entamoeba hartmanni*, *Loeschia histolytica* and *Endamoeba dysenteriae*.

The diseases caused by amebic infection are amebiasis or amebic dysentery, and amebic abscess of the liver

The ameba carrier state is chronic, its duration being measured in months rather than in days and weeks as it is in bacillary dysentery

The sources of infection are the carrier or asymptomatic contact and the chronic convalescent patient who are passing infective cysts. In acute dysentery encystment does not occur, either because conditions for cyst formation are unfavorable or because the trophozoites are discharged too rapidly to permit encystment. Hence patients who have the disease in acute form are not important sources of infection, since the trophozoites rapidly perish outside the body, and are destroyed by the gastric secretions if they reach a new host. The mature cyst is apparently the infective form

Endamoeba histolytica may be observed in the feces in three morphologic stages: (1) the trophozoite, (2) the precystic and (3) the cystic.

Life Cycle The life cycle of *Endamoeba histolytica* is comparatively simple The

formation of infective cysts in the large intestine is followed by their passage in the feces, their extracorporeal existence and their ingestion by a new host.

When amebae are ingested by man, the mature cysts pass unaffected through the stomach. In the lower part of the small intestine the cyst wall disintegrates, liberating a four-nucleated ameba, which divides ultimately into eight small trophozoites These small active amebae move downward to the large intestine, where they invade the mucosa, submucosa and muscular tissues of the intestinal wall, aided by the action of their cytolytic ferments and by their ameboid movements. From the intestinal wall the amebae may spread to secondary sites They may reach the liver by way of the portal vein, thence by the blood to the lungs, brain and other organs, where they multiply in the tissues.

The pathologic lesions of amebic infection of the intestinal wall are of three types: (1) early minute nodular flasklike cavities, (2) irregular crateriform ulcers with ragged edges and (3) communicating sinuses between adjacent ulcers

The primary lesions are largely confined to the large intestine, a few may be situated in the lower part of the ileum near the ileocecal valve The lesions are often scattered throughout the colon. Isolated infected regions of the colon are situated in the following order of frequency cecum, ascending colon, rectum, sigmoid and appendix

The secondary lesions usually occur in those who have active primary lesions However, hepatic abscesses have been found in patients who gave no history of dysentery Chance determines the establishment of a secondary infection

In the liver the amebae first cause hepatitis and then dissolve the hepatic cells, producing single or multiple abscesses, usually in the right lobe The living amebae are continually invading the marginal tissue As the abscess increases, its wall thickens and the contents become a viscid chocolate-colored or reddish mass of hepatic cells, erythrocytes, bile, fat and other products of tissue dissolution There is usually only one abscess, but it may reach a large size and even rupture into the peritoneum or pleura Secondary bacterial infection produces purulent changes

About one half of the dysenteric patients who come to necropsy show major or minor involvement of the liver since the presence of amebae in the liver does not invariably mean a hepatic abscess Once within the circulation, amebae may be carried from the liver to any organ of the body, such as the brain, lungs, and spleen, there are instances, but not without question, of the involvement of urinary bladder, testes, epididymides, lymph nodes, skin, bones and joints

SYMPTOMS The ordinary state of infection is an equilibrium between parasite and host, and the typical infected individual is an asymptomatic carrier The contact carrier maintains a low-grade infection, but whenever his resistance is lowered, he may succumb to the disease The convalescent carrier has recovered from dysentery, but is subject to clinical relapse Clinical dysentery develops in about 1 of 10 infections The incubation period varies from a few days to months and even years, since clinical dysentery may develop at any time in asymptomatic carriers. The period of incubation in the severe and highly fatal Chicago epidemic of 1933-1934 was less than 1 week in 6 7 per cent of 495 cases, less than 4 weeks in 64 7 per cent (mean 12 days) and less than 8 weeks in 91 per cent.

The infected person does not manifest symptoms, but there is often an awareness of slight discomfort The patient may have mild toxemia, or may suddenly be seized with dysentery

Acute dysentery varies in severity from the rare fulminating illness with marked toxemia to the mild attack with spontaneous recovery The onset may be sudden with acute abdominal pain, nausea, vomiting, fever (temperature 100 to 102 F, 37 8 to 38 9 C) and occasionally chills; more often it is insidious and is preceded by attacks of mild or severe diarrhea. At the height of the attack the patient may have 15 to 20 or more daily movements of blood, mucus and, in severe cases, bits of necrotic mucosa

The patient who has *chronic dysentery* manifests symptoms of dysentery only during exacerbations. At all other times the bowel movements are normal except for the usual constipation or minor intestinal irregularities that almost everyone has In

4. *Trichomonas hominis*. All intestinal trichomonads, irrespective of whether they possess three, four, or five anterior flagella, are designated here as *Trichomonas hominis*. At least three forms have been described as distinct species, *Trichomonas fecalis*, *Trichomonas hominis* and *Pentatrichomonas ardin delteili* (see *Trichomonas vaginalis* in Chapter 7).

Trichomonas hominis, probably nonpathogenic, causes intestinal trichomoniasis

Trichomonas elongata (*Trichomonas buccalis*) is nonpathogenic to man.

The Superfamily Oxyuroidea (Nematoda). The members of the superfamily Oxyuroidea are small, pin-shaped, meromyarial nematodes parasitic in the large intestines of vertebrates The two species which occur in man, *Enterobius vermicularis* and *Syphacia obvelata*, belong to the family Oxyuridae

1. *Enterobius vermicularis* This parasite causes *pinworm infection* (enterobiasis, oxyuriasis). Man is the only known natural host of *Enterobious vermicularis*.

Of cosmopolitan distribution, *Enterobius vermicularis* is a small, round worm which inhabits the rectum, bladder and the adjacent portions of the large intestine of man.

Oviposition does not occur until the female worm is stimulated by contact with air, the ova are not commonly laid in the intestine. The female releases her hold on the intestinal mucosa, and either is passed in the feces or migrates at night from the anus and crawls actively in the perianal and perineal regions, even entering the vagina or more rarely the bladder The ova are expelled in masses and are left behind as the worm advances from place to place over the perianal and genitocrural folds Occasionally the female worms cause itching If the worm dries, it explodes with showers of ova

Outside the host an infective larva develops within the shell in a few hours The hands, particularly beneath the fingernails, become contaminated with adherent ova through handling the perianal regions Thus infective ova are readily transferred to the same or another host either directly by hand to mouth or indirectly through food and drink The ova that adhere to night clothes and bed linens may also be transmitted by the hands.

Upon ingestion the embryos are liberated in the duodenum

The presence of the parasite is suspected clinically in children who manifest intense nocturnal perianal itching Diagnosis is made by finding the adult worms or ova Often the first evidence of infection is the discovery of the adult worms in the feces, particularly after enemas In the feces the worms must be differentiated from fly larvae The ova are seldom found in the feces even with concentrative methods Ova are frequently obtained from fingernail scrapings.

Diseases of the Colon Due to Trauma, Physical Agents and Static Abnormalities. Rupture of the Colon and Rectum. Spontaneous rupture of the colon probably does not occur unless there is disease of the intestinal wall When rupture does occur, it is due primarily to a rise in intraluminal pressure produced by air or water, foreign bodies, external violence, extracolonic diseases, or trauma to the wall of the bowel.

Perforation of the bowel during the course of sigmoidoscopic examination may not be suspected until the signs of diffuse peritonitis become manifest In other instances of tears the wound may be seen in the bowel, usually at or near the rectosigmoid. The tear is often manifested by a rush of air inward during expiration as soon as the hole is made.

If there is evidence of trauma, there usually is a history of sudden onset of pain of great severity, with the rapid development of the signs of shock and peritonitis The signs of shock—boardlike rigidity, absent peristalsis and, perhaps, evidence of pneumoperitoneum—are present In some instances the symptoms and signs of peritonitis may be delayed from a few hours to a day after the wound in the bowel has occurred

A roentgenologic examination of the abdomen and the demonstration of pneumoperitoneum are diagnostic of a perforated, air-containing viscus.

As soon as a diagnosis of rupture of the colon is made, operation must be undertaken at once, delaying only for preparation of the patient and treatment for shock. The prognosis is always grave.

Foreign Bodies in the Intestine and Colon. Many foreign bodies, especially such small objects as fish bones, tacks, bits of glass and parts of oyster or egg shells, are ingested unknowingly.

The desire to conceal objects or to destroy incriminating evidence may lead individuals to swallow foreign bodies or introduce them into the rectum Instances in which drug addicts have concealed narcotic vials in the rectum are common.

During the course of examination or treatment an instrument may slip into the rectum or be swallowed. Stomach tubes may be completely swallowed or metal tips become dislodged in the stomach Rectal thermometers and nasal suction tubes are occasionally recovered from the sigmoid or the rectum.

A foreign body may remain in the lumen of the bowel for years, giving rise to no symptoms Swallowed foreign bodies may be held up at those sites in the alimentary tract which are normally narrow, fixed, or angulated; these sites include the pylorus, duodenum, ileocecal valve, hepatic and splenic flexures, rectosigmoid and rectum

The symptoms of foreign body in the intestine and colon depend on the site of lodgment of the object, the character and size of the object, and the presence or absence of complications

The history is important but often is unreliable in diagnosis of a foreign body in the colon or rectum Frequently the patient does not know that a foreign body has been swallowed Patients who have mental aberrations from anesthesias, hypnotics, or narcotics, or those who are psychotic may swallow foreign bodies.

Foreign bodies lodged in the cecum may simulate appendicitis. The anal crypts may act as repositories for small foreign bodies, severe proctitis and even abscess may result

If the foreign body is irritating or of a type capable of causing lacerations of the gastrointestinal mucosa, a severe gastroenteritis may ensue. Large foreign bodies impacted in the rectum may cause complete obstruction of the bowel associated with abdominal swelling, rectal pain and bleeding, and tenesmus

The clinical findings on examination may resemble those of an abscess, appendicitis, diverticulitis, general peritonitis, intestinal obstruction, proctitis, or a malignant mass

Digital examination is an important procedure when objects are suspected of being in the rectum If the object is high in the rectum, proctosigmoidoscopic and roentgenoscopic examinations are valuable The barium always is administered as an enema

The diagnosis is made by finding the foreign body

The complications of foreign bodies in the intestinal tract are hemorrhage, laceration of the bowel, perforation with peritonitis or abscess formation, fecal, rectal, rectovaginal and rectovesical fistulas, cryptitis, chronic granulomas, fecal impactions and intestinal obstruction. Some of these complications may occur as the result of attempts at removal

Obstruction to the bowel may occur when the foreign body is large or when it acts as a center for the deposition of a fecal concretion, such as occurs in obstruction by a large gallstone

A foreign body in the intestine or rectum which remains fixed and will not pass on should be removed surgically

Factitial Proctosigmoiditis. When irradiation therapy is necessary in the rectal or genital regions, it is well to tell the patient and the family of the possibly serious effects which may follow the use of radium or roentgen therapy. If this is done,

excessive terms will not be required for naming the possible complications (see Chapter 19).

Bleeding from the rectum may appear at any time during the period of the radium treatment to 6 years after irradiation therapy. *The rectal bleeding is increased* by defecation, rectal examination, or instrumentation. The rectal bleeding may be uncontrollable, so that the patient bleeds to death. A frequent and very urgent desire to defecate is commonly present during the stage of active proctitis and bleeding Pain in the rectum may be severe and may radiate to the sacrococcygeal region and to the thighs and groins The pain, like the bleeding, is intensified by defecation and by standing or walking. Fever and fistulous communications with the vagina and urethra are severe complications which often lead to confinement in bed and emaciation and finally death

The general examination in those who have had roentgen rays or radium applied to the skin reveals areas of induration, telangiectasis and pigmentation of the sites of exposure to the rays

On rectal examination of those who have been treated for carcinoma of the cervix, there may be a palpable induration or a hard tumor on the anterior wall of the rectum In some there is an ulcer with a crater, with or without a surrounding mass Palpable annular strictures are common. These strictures are often present in those who have rectovaginal, rectovesical, perineal or perianal fistulas and a recurrence or an extension of the malignancy.

The proctologist may report that the mucosa appears reddened and edematous and bleeds easily following the slightest trauma Later the mucosa is described as indurated and showing telangiectasis.

Fecal Impactions of the Colon and Rectum. Fecal impaction is commonest in the rectum, but it may occur in the sigmoid or cecum and even in the transverse colon. There is usually one impaction which increases proximally from the initial impaction

Some persons regularly pass several days without an evacuation of the bowel. The addition of excessive tension and fatigue plus insoluble medications, bulk-forming cathartics and undigested food particles may result in a great mass of feces accumulating in the colon or rectum before distress occurs.

Other persons do not yield to the desire to defecate and as a consequence there is a gradual dilatation of the rectum, with eventually a loss of the defecation reflex. Under these circumstances the patient becomes unaware of the presence of feces in the rectum until a very large fecal mass accumulates, and impaction may be the consequence

Often those who have a large part of the body enclosed in a cast, or elderly patients who are confined to bed, have fecal impactions

Fecal impactions are prone to follow barium meals if the barium is not emptied from the bowel.

Anal lesions or anorectal manipulations or operations which cause pain on defecation may predispose to impaction of feces

Pregnancy, pelvic and large abdominal tumors, and ascites may act as predisposing causes of fecal impaction. This complication of constipation is perhaps most likely to develop in multiparae and aged individuals in whom the perineal and pelvic supports are relaxed.

Megacolon is an effective but a rare cause of impaction

The desire for defecation is always the most persistent and severe symptom. Often the first and sometimes the most persistent symptom of an impaction may be what the patient considers to be a diarrhea This paradoxical diarrhea is in reality a tenesmus with discharge of small amounts of mucus and feces. The abdominal pain or cramps which are present in the beginning often subside or become intermittent after the impaction has existed for a day or two

Stercoromas can achieve great size, causing swelling of the abdomen and large, easily palpable masses. The commonest palpable abdominal tumor is constituted of

the commonest material in the abdomen—feces On palpation of the abdomen a stercoroma feels much harder than a carcinoma, and the tumor is freely movable. Constitutional symptoms, particularly anemia and loss of body weight, are usually absent in patients who have stercoroma When a stercoroma is felt digitally, it should be broken up into several parts

Fecal impactions in the rectum are easily diagnosed by means of digital examination. When the impaction is in the lower part of the sigmoid, direct visualization by means of the sigmoidoscope often is possible Fecal impactions or stercoromas in the transverse colon or in the cecum may not be easily diagnosed roentgenologically.

The most serious complication of fecal impaction is perforation of the wall of the bowel with general peritonitis ensuing or abscess formation.

Melanosis Coli. The pigments in melanosis coli are melanins or epithelial pigments The entire colon may be involved, with an abrupt demarcation and ending at the ileocecal valve Pigmentation in some patients is most marked in the cecum and ascending colon, and in others is more intense in the descending colon.

The incidence of these pigmented bowels is not known, but the condition is not rare. In some instances of extreme pigmentation the degree of coloration is the same throughout the rectum and sigmoid The condition occurs between the ages of 30 and 60 years, in both men and women and in both Negroes and whites

Obstinate constipation is present and often is the reason that the patients seek medical advice Cascara sagrada is taken either alone or in combination with alophen, aloin, or rhubarb by many of these persons. Melanosis coli occurs, however, in those who have not taken cascara sagrada

Melanosis coli cannot be held responsible for any known complaint or symptoms It does not predispose to malignancy.

Diseases of the Colon Due to Unknown Causes. *Chronic Ulcerative Colitis.* This disease is called also colitis gravis, chronic suppurative colitis, idiopathic ulcerative colitis, nonspecific ulcerative colitis and thrombo-ulcerative colitis. This is not a common disease

The cause is unknown There are certain factors which seem to be of etiologic importance but cannot be proved These are the so-called constitutional, infectious, allergic and psychogenic factors

The constitutional factors which might be of etiologic importance comprise the possible intrinsic systemic abnormalities, such as those of endocrine glands, and the allergic, psychogenic and neurogenic disturbances. Endocrinal influences or metabolic states, however, seem to play no part in the etiology of ulcerative colitis The conditions requisite for diagnosis of an allergic state are not fulfilled by ulcerative colitis unless the patient accidentally has both conditions

The course of any chronic disabling disease is affected by psychogenic factors [illegible] Before the present [illegible] cians were aware [illegible] their great influ- [illegible] opinion arise in regard to the order of appearance of the emotional disturbances and the ulcerative colitis On this point and, consequently, on the etiologic importance of emotional [illegible]

[illegible] support either of these as possessing great etiologic possibilities

[illegible]

reac [illegible]

The [illegible]

The [illegible] between bacillary dysentery and ulcerative colitis are the variation in onset and duration and the lack of evidence of infectivity or contagion in ulcerative colitis

The terms colitis gravis, nonspecific ulcerative colitis and idiopathic ulcerative colitis are used to describe a diffuse hyperemia, granular in appearance, of a segment or all of the colonic mucosa which progress to ulceration and scar formation

In the early stages of the disease there are hyperemia and hemorrhages under the mucosa and submucosa and ensuing shallow erosions and deep ulcerations The ulcerations are irregular in size and location. In the rectum the ulcers tend to coalesce, denude and undermine the mucosal surface and leave mucosal tags. As the disease becomes more chronic, there are polypoid and proliferative changes. The muscular layer is thickened from edema A replacement of the muscular layer by inflammatory tissue ensues with contraction of the scar tissue which produces narrowing deformities of the lumen of the bowel and shortening of its length Strictures, perforations, hemorrhages and obstructions are common

Ulcers situated proximally to the rectum in the sigmoid, descending colon, transverse colon and ascending colon tend to be elliptical with their long axes parallel to the long axes of the bowel Circular groups of ulcers may follow the course of the muscle fibers Often there are thinned spots of the intestinal wall which may perforate Likewise there are hyperplastic areas of mucous membrane which have an ample blood supply and participate in the formation of pseudopolyps.

The entire rectum and colon are frequently involved by the disease Occasionally the distal portion of the ileum is affected along with the colon One or more segments of the colon may be involved without disease of the rectum. When only parts of the colon are involved, the condition is termed regional or segmental ulcerative colitis If only the rectum and the sigmoid are involved, this is termed proctosigmoiditis On the basis of segmental distribution of ulcerative colitis Bargen has classified the disease accordingly into four groups These groups serve mainly as a basis for the study of many cases

Ulcerative colitis is cosmopolitan. It is less prevalent in the warmer portions of the United States of America than in the northern sections

The onset of ulcerative colitis may occur at any age but usually before 40 years There are no sex preferences It shows no house, community or family incidence. The presence of more than one case of ulcerative colitis in the same family is unusual, but there are exceptions.

SYMPTOMS. The onset is characteristically insidious and may be unassociated with diarrhea In rare instances constipation may prevail throughout the course of the disease In many cases, however, the passage of 3 to 5 stools a day may constitute the first symptom, and the appearance of bloody mucus on the outside of the stools is an almost constant early symptom In some instances the first known symptom of the disease may be abrupt, with diarrhea, and in some without the gross appearance of blood in the feces In the onset of the acute fulminating type of the disease the patient may have almost continuous liquid evacuations, composed almost entirely of blood, pus and mucus In these the involuntary passage of the bowel movement is common

Abdominal pain, colicky or crampy in type, and often confined to the lower abdominal quadrants, almost always accompanies the bloody dysentery. The pain occurs with the desire for defecation and is relieved in some, while in others it is made worse, by a bowel evacuation Rectal tenesmus is constant and fatiguing and afflicts all of those who have rectal involvement and frequent bowel movements The irritation of the anus by the frequent bowel motion may create fissures and if so the anal pain becomes severe and fatiguing.

Anorexia, fullness, nausea, epigastric discomfort and often vomiting are commonly present. Besides their importance in the addition to the patient's discomfort, [illegible] normal

[illegible]

symptoms than to the severity of the disease unless there is [illegible]

Chronic ulcerative colitis is characterized by remissions and relapses of symptoms The recurrences are usually in the form of acute exacerbations of the disease

However, there are chronic forms of the disease which are continuous Relapses of chronic ulcerative colitis seem to result from (1) infection in the upper part of the respiratory tract, (2) dietary indiscretions and partaking of alcoholic drinks, (3) fatigue, operative procedures, gestation, generalized or localized infections and (4) emotional or psychic disturbances.

The symptoms of chronic ulcerative colitis may be changed on any day from the time of its inception until death by the appearance of a complication. The complications are numerous, and in view of the seriousness of the disease, all complications likewise are serious

A *fibrotic constriction* of the lumen of the diseased colon is one of the commonest complications of ulcerative colitis Stricture may develop in any segment of the colon, but seems to occur most often in the rectum These strictures are often manifested by symptoms of obstruction to the emptying of the colon or rectum.

Massive hemorrhage is common However, more commonly there is prolonged and profuse bleeding. Hemorrhages are, therefore, an important complication of this disease

Subacute or chronic *slow perforations* may produce an extensive tissue reaction without actual abscess formation but may terminate in formation of abscess and fistula.

The infiltration of the tissues due to either perforation or permeation may result in local *abscess formation* Such a collection of pus may drain into the rectum with *sinus formation*, it may point and drain outside the anus with resulting *fistulization*, it may drain through the vagina (rectovaginal fistula), or it may drain into the bladder (rectovesical fistula) Occasionally a large pelvic abscess or localized peritonitis occurs This complication may prove serious and may require drainage. However, the surgeon should be prevailed on not to be hasty to lance an apparent abscess, for the abscess may open elsewhere despite the surgeon's efforts.

During the course of ulcerative colitis and in acute exacerbations, usually while the patient is confined to the bed, *involvement of the joints* is frequently observed. The articular symptoms improve with improvement of the colitis and recur with exacerbations of the colonic disease Arthralgia and myositis in association with ulcerative colitis are common, particularly after prolonged high fever. Such involvement of joints perhaps is no commoner among patients who have chronic ulcerative colitis than among patients who have any other chronic disease which is characterized by the presence of fever, pain and confinement to the bed. The pain is so severe in many of these patients that they lie quietly except when disturbed by bowel movements

EXAMINATION The skin of a patient who has ulcerative colitis is usually normal except during periods of exacerbations when fever and dehydration are present. The skin is then dry and loose because of loss of water and electrolytes and subcutaneous tissues Evidences of vasomotor instability may be prominent.

The condition of a patient who has been seriously ill or who has sitophobia is often complicated by nutritional deficiencies In these patients changes in the skin [illegible]

[illegible] recur

[illegible] esions, described variously as phagedenic ulcers, phagedenic pyoderma, chronic burrowing ulcer and pyoderma gangraenosum, occur These lesions may follow surgical operations and the prolonged fever in association with ulcerative colitis. Although rare, phagedenic lesions are extremely serious.

Loss of weight, pallor, and weakness are evident in most of those who have had the disease for a long time (months, sometimes years).

The tongue, mouth and eyes rarely show changes associated with nutritional deficiency or suggestive of allergy.

The terms colitis gravis, nonspecific ulcerative colitis and *idiopathic ulcerative colitis* are used to describe a diffuse hyperemia, granular in appearance, of a segment or all of the colonic mucosa which progress to ulceration and scar formation.

In the early stages of the disease there are hyperemia and hemorrhages under the mucosa and submucosa and ensuing shallow erosions and deep ulcerations. The ulcerations are irregular *in size and location. In the rectum the ulcers tend to coalesce, denude* and undermine the mucosal surface and leave mucosal tags. As the disease becomes more chronic, there are polypoid and proliferative changes. The muscular layer is thickened from edema. A replacement of the muscular layer by inflammatory tissue ensues with contraction of the scar tissue which produces narrowing deformities of the *lumen of the bowel and* shortening of its length Strictures, perforations, hemorrhages and obstructions are common.

Ulcers situated proximally to the rectum in the sigmoid, descending colon, transverse colon and ascending colon tend to be elliptical with their long axes parallel to the long axes of the bowel Circular groups of ulcers may follow the course of the muscle fibers Often there are thinned spots of the intestinal wall which may perforate Likewise there are hyperplastic areas of mucous membrane which have an ample blood supply and participate in the formation of pseudopolyps.

The entire rectum and colon are frequently involved by the disease. Occasionally the distal portion of the ileum is affected along with the colon One or more segments of the colon may be involved without disease of the rectum When only parts of the colon are involved, the condition is termed regional or segmental ulcerative colitis. If only the rectum and the sigmoid are involved, this is termed proctosigmoiditis On the basis of segmental distribution of ulcerative colitis Bargen has classified the disease accordingly into four groups These groups serve mainly as a basis for the study of many cases

Ulcerative colitis is cosmopolitan It is less prevalent in the warmer portions of the United States of America than in the northern sections

The onset of ulcerative colitis may occur at any age but usually before 40 years There are no sex preferences It shows no house, community or family incidence The presence of more than one case of ulcerative colitis in the same family is unusual, but there are exceptions.

SYMPTOMS. The onset is characteristically insidious and may be unassociated with diarrhea In rare instances constipation may prevail throughout the course of the disease *In many cases, however, the passage of 3 to 5 stools a day may constitute* the first symptom, and the appearance of bloody mucus on the outside of the stools is an almost constant early symptom In some instances the first known symptom of the disease may be abrupt, with diarrhea, and in some without the gross appearance of blood in the feces In the onset of the acute fulminating type of the disease the patient may have almost continuous liquid evacuations, composed almost entirely of blood, pus and mucus In these the involuntary passage of the bowel movement is common

Abdominal pain, colicky or crampy in type, and often confined to the lower abdominal quadrants, almost always accompanies the bloody dysentery The pain occurs with the desire for defecation and is relieved in some, while in others it is made worse, by a bowel evacuation Rectal tenesmus is constant and fatiguing and afflicts all of those who have rectal involvement and frequent bowel movements The irritation of the anus by the frequent bowel motion may create fissures and if so the anal pain *becomes severe and fatiguing.*

Anorexia, fullness, nausea, epigastric discomfort and often vomiting are commonly present. Besides their importance in the addition to the patient's discomfort, they are responsible for inability to eat and thus for difficulty in maintaining normal nutrition The loss of body weight and strength is related more to severity of these symptoms than to the severity of the disease unless there is prolonged high fever

Chronic ulcerative colitis is characterized by remissions and relapses of symptoms The recurrences are usually in the form of acute exacerbations of the disease

oped disease the mucosa becomes red and edematous, presenting a characteristic pitted, granular appearance. Usually there is a constant oozing of blood from the surface while the examination is being made.

Roentgenologic study after a barium enema has been given may be considered as an extension of the endoscopic examination and necessary for diagnosis of the extent of the disease.

The prognosis for life, despite the many complications, is generally good. The mortality rate is greatest during the first year of the disease and decreases thereafter. The expectation of life improves with the passage of time. The prognosis for cure is totally bad. No one can ever be sure that the disease has been cured as long as the colon remains in the abdomen

In those whose symptoms are not acute in the beginning, the disease is likely to continue as a subacute or chronic form, or to disappear entirely. Prognosis is poor in those who have a fulminating or a chronic continuous type of the disease. In those in whom the disease had an insidious mild onset, those who have definite remissions and relapses of symptoms, and those in whom the disease remains confined to the rectum or rectosigmoid, the prognosis is good, and many are able to adjust their lives accordingly That is, about 3 of every 4 patients should be rehabilitated for varying periods of time, none are ever cured medically. Some recover spontaneously

A free perforation of the colon is not an indication for operation, for suturing of the diseased bowel is impossible Carcinoma and stricture causing obstruction require surgical treatment Some severe perianal and perirectal infections progressively extend until the fecal current must be diverted Polypoid hyperplasia is not an indication for operation If an adenomatous change in the polypoid tissue is demonstrated on histologic study, operation should be advised

If surgical intervention is advised, it seems that the practicable procedure is ileostomy and colectomy by stages.

Tumors of the Colon and Rectum. ***Benign Tumors.*** Many of the benign lesions of the colon are polyps The terms polyp and polypous refer to a projective growth from a mucous surface They designate a form or shape of a lesion without regard to histologic structure

Certain polypous or polypoid lesions which appear in the colon and rectum are congenital in origin These lesions comprise polyps, teratomas, dermoid cysts, enterogenous cysts, angiomas, lymphangiomas and neurofibromas

In the immediate development of the *acquired* polypous or polypoid lesions of the colon and rectum there are certain factors which appear to be instrumental: hereditary predisposition to grow the tumors, primary epithelial hyperplasia, subsequent chronic irritation, inflammation, and finally primary subepithelial change

Polyps. The common type of polyp of the colon and rectum is an adenoma. However, it is incorrect to assume that a polyp is an adenoma until histologic study has proved it so

Erdman subdivided colonic polyps (adenomas) on the basis of their clinical behavior, etiology and histologic appearance into (1) the adolescent (congenital, disseminated) type and (2) the adult (acquired) type This subdivision is adequate for clinical description

In about one half of those who have multiple polypoid lesions of the bowel there is a distinct *familial disposition* indicating a factor of morbid heredity. Probably without

Fever is present with each acute exacerbation of the disease. In some patients there is often a continuous low grade of fever over long periods The temperature may rise to 103 or 104 F (39.4 or 40 C) each day for several weeks and in some for months, subsiding only to recur again.

On abdominal examination tenderness, usually generalized throughout the abdomen, is always present Some distention of the abdomen may be present. The results of palpation of the colon often are not significant. Rarely is the liver or the spleen palpable

Rectal examination and digital palpation of the mucous membrane often do not reveal any abnormality Edema and strictures may be felt. Polyps or carcinoma may be palpated if present The coarse, granular changes in the mucosa described by the endoscopist usually cannot be palpated Determination of the presence or absence of fistula of the rectum or the vagina can be made with aid of good history and light at the time of digital or endoscopic examination

The sigmoidoscopic examination reveals the granular, ulcerative, hyperemic appearance of the mucosa and the degree of contraction of the lumen, strictures, fistulas, fissures, and in some instances pseudopolyps The roentgenologic examination reveals the abnormalities in the sigmoid and the rest of the colon

Polyps and pseudopolyps are commonly found The pseudopolyps may have the appearance of genuine polyps Pseudopolyps seem to arise from shreds of mucous membrane which have a sufficient blood supply to remain alive and grow after being torn loose on two or three sides from the submucosa of the bowel and regions of hyperplastic mucosa which may grow until a polypoid mass is formed These are diagnosed by means of sigmoidoscopic and roentgenologic examinations *Pseudopolyps are differentiated from true polyps by microscopic examination of sections of the polyp*

The detection of carcinoma in chronic ulcerative colitis is made by digital or endoscopic examination of the rectum, or roentgenologic study of the colon after *barium enema Histologic study is required to confirm this diagnosis*

Free perforation with generalized peritonitis is rare in ulcerative colitis Perforation occurs in the extremely acute fulminating forms of colitis and in association with stricture formation Diagnosis of free perforation is based on the presence of an *acute peritonitis*

Measurable hepatic dysfunction rarely accompanies ulcerative colitis

Amenorrhea is the rule during the stage of activity of the disease When the disease begins in childhood, sexual development may be retarded and varying degrees of infantilism result.

Complete blood counts and hemoglobin determinations reveal presence or absence of anemia Many patients who have ulcerative colitis are anemic The degree of anemia is dependent on the amount of blood lost and the degree of iron deficiency. The total and differential leukocyte counts are frequently normal even during severe exacerbations of the disease. Leukocytosis may be present when complications arise

DIAGNOSIS. Sigmoidoscopists are in essential agreement that the following appearances of the mucous membrane of the rectum and rectosigmoid prevail in the early stage of chronic ulcerative colitis, and that when present these findings are diagnostic: The mucous membrane may be reddened in appearance. Application of a cotton swab may cause an elevation of the membrane In other instances the membrane has a granular appearance and may show a few fine bleeding points A mottled discoloration due to petechiae connected by a fine weblike network may be present. As the disease advances, there is a general hyperemia and the mucosa appears swollen After the surface is swabbed, it appears granular and there are bleeding points. Ulcerations may or may not be present. In instances of fully devel-

¼ to ½ inch (0 6 to 1 3 cm.). However, very large polyps may be present without discomfort.

About one fourth of all patients who have the disease complain of some form of abdominal distress. The discomfort varies widely in situation, character and severity. It is a cramplike pain which extends across the midsection of the abdomen and which is increased during and after bowel movements

Inflammation or ulceration often is present The development of characteristic ... When ... h very ... usual

A polypoid lesion may attain sufficient size to occlude the lumen of the bowel or it may so interfere with normal peristalsis as to cause intussusception. Intestinal obstruction may therefore be the reason for the patient to seek relief, and the polyposis is discovered at the time of surgical operation Frequently the obstructive phenomena occur in acute short-lived episodes which disappear spontaneously.

Pedunculated rectal growths may be extruded through the anus and on rare occasions the polyp may be spontaneously expelled There are records of patients who passed from the rectum the only polyp present Usually another polyp will grow in the same place at a later date

Examination Polyps, even small ones, under favorable conditions may be palpated The most favorable site for the palpation of a polyp is on the posterior surface of the rectum over the sacrum

When polyps are brought into view by the endoscope, or when their relief is depicted on the roentgenogram by contrast media employed by the roentgenologist, every conceivable variation in size and shape of polypoid lesion may be present, ranging from small excrescences on the mucous surface to large pedunculated masses The polyps may be widely disseminated over the luminal surface of the colon, there may be aggregations of polyps limited to one or more segments, often to the rectum or perhaps to a flexure, or there may be one polyp in the entire colon, or a few single polyps in the rectum

The status of a given polypoid lesion, whether *benign* or *malignant*, can be determined only by biopsy and histologic study The size or shape of a lesion is not significant The malignant status of the polyp may be evaded by reporting it as an adenocarcinoma in an adenoma The gross appearance of polyps which have undergone cancerous transformation often reveals ulceration, nodular irregularity, fixation, or induration There is much evidence which strongly favors the close relationship of polyposis to cancer Polyps are often found in carcinomatous colons

Diagnosis In the diagnosis the hereditary or familial features are obtained from the history. In patients who have the heredofamilial variety of polyps, rectal palpation may be diagnostic

... nosis is certain when a polyp has been examined microscopically The prognosis depends on complications, since the complications are the same in both the adolescent (congenital, disseminated) types and the adult (acquired) type

Lipomas Lipomas constitute the second commonest benign tumor of the gastrointestinal tract Despite this incidence, lipomas of the intestines are rare. They occur more frequently in the colon than elsewhere and they are somewhat commoner in women than in men.

Symptoms are commonly absent Intussusception occurs in about one third and bleeding in about one fourth of the patients who have any symptoms

individuals, representative of 5 generations of one family of German extraction, who have or have had hereditary and familial polyposis of the colon. In all of these the symptoms occurred before 40 years of age and there has been no sex preference

In many young patients no such evidence of morbid heredity is present In some there may be a limited familial incidence. One or two members of the family may be known to have had polyps of the rectum or colon However, about one half of those who have polyposis cannot present any genealogic evidence of polyposis.

Acquired polyps of the colon generally occur in older patients than those affected by congenital polypoid disease Polyps have been encountered in persons of ages ranging from 16 to 87 years; the most frequent occurrence is in persons in the fifth and sixth decades. In the large bowel they are situated, in order of frequency, in the cecum, ascending colon, sigmoid, transverse colon, rectum, and descending colon The polyps may be present singly or multiply or may occur profusely in segments of the colon

The actual incidence of these lesions may be at least partially appreciated from the data accumulated from studies made by Jackman and Mayo "In a series of 2,784 necropsies done at the Mayo Clinic in the five-year period from 1935 to 1939 inclusive in cases in which the patients had died of some other condition not related to the colon, 14 7 per cent of the 1,757 males in the group and 9 0 per cent of the 1,027 females were found to have polyps of the large intestine. Bear in mind that this study took in all ages from newborn to the age of 90 years. The peak incidence was found in persons who were in the age group from 60 through 69 years, in this group 26 4 per cent of 421 men and 15 4 per cent of 195 women had polyps. It could well be assumed that had these patients not succumbed to some other disease, the polyp would eventually have developed into carcinoma "

Polyps are to be found with surprising frequency in colons which are already the seat of carcinomas Also it seems that there is an increased incidence of polypoid lesions in association with chronic ulcerative colitis aside from the so-called pseudopolyps

Symptoms Patients who have uncomplicated polyposis may not be ill. The abdominal examination does not reveal the presence of any abnormal condition in most of those who have heredofamilial forms of the disease until complications are present

There is considerable evidence to indicate that polyps of the rectum and colon may be present for a long time without producing symptoms For instance, McKenney presented evidence which suggests that the lesions in congenital polyposis are present at a very early age and progressively grow before sufficient symptoms are present to require an examination

As many as half of the patients who have multiple polypoid lesions of the colon may have had symptoms for 10 years or longer before the diagnosis is made The duration of symptoms varies from 1 day to 7 years, in the majority, however, from 6 months to 3 years

The symptoms which may be produced by polyps are like those for all of the benign tumors of the colon They are dependent on several factors the size, the situation, and the number of polyps and the presence or absence of complications

Blood in the stools is complained of by two thirds of all patients who are found to have one or more polyps of the rectum and colon As a rule, the bleeding is [illegible] more than is present in many cases [illegible] ents discovered to have polyps will [illegible] aracterized by acute exacerbations [illegible] Like the bleeding, it is inconstant, intermittent and not severe, it may be accompanied by pain but often the diarrhea is the only symptom .

[illegible] and urgency on defecation with an unsatisfactory feeling of incom- [illegible]

spread has extended to the extrarectal tissues (type B Dukes); and (3) those in which metastasis is present in the regional lymph nodes (type C, Dukes). This classification supports an observation, often expressed by William Worrall Mayo, that tumors which project toward the lumen are more benign, whereas deeply excavated ulcers in tumors which grow away from the lumen are more malignant

Broders' classification is an estimate of the degree or grade of malignancy based on the rate of growth; tumors are divided into four groups depending on the percentage content of differentiated cells as compared with undifferentiated cells observed microscopically (degrees of anaplasia), grade 1 indicating the lowest degree of malignancy and grade 4 the highest. About 3 of every 4 carcinomas of the colon are of Broders' grade 1 or 2.

Metastasis occurs from cancer of the colon in three ways (1) by direct extension to contiguous structures, (2) through hematogenous dissemination to distant sites and (3) by way of the lymphatics to regional or distant lymph nodes

The regional lymph nodes and the liver are the common sites for metastasis of cancer of the colon. Distant and unusual sites of metastatic lesions comprise the lungs, bones, pancreas, renal capsule, spleen, adrenal glands, heart, thyroid gland, breasts, brain, duodenum, and mediastinum

In regard to the nodes involved, there may be retrograde spread and interrupted spread. Normal lymph nodes may intervene between the primary site and the next nearest involved node. In the colloid type of adenocarcinoma nodal metastasis is approximately two and one-half times as great as in the noncolloid type The inguinal lymph nodes are rarely involved in carcinoma of the rectum

Carcinoma of the colon tends to appear in older persons with a little greater frequency than does carcinoma of the rectum. Only 1 of every 20 who have cancer of the rectum and colon will be less than the age of 30 years. Two men for every woman have carcinoma of the colon or rectum

SYMPTOMS The average duration of time which elapses from what is thought to have been the onset of symptoms to hospitalization is around 8 months for those who have cancer of the rectum and 1 year for those who have cancer of the colon. The duration of symptoms before diagnosis is made in patients who have carcinoma of the right side of the colon is about fifteen months

Any symptom sufficient to attract attention to colonic malfunction may be a symptom of a cancer therein Completely asymptomatic cancers of the colon are often discovered by digital, proctoscopic and roentgenologic examinations When symptoms of cancer of the colon are present, they are usually enumerated as altered bowel function, abdominal cramps, pain, and abnormal evacuations of the intestinal contents

The altered function of the colon seems to be a disturbance in the motor functions manifested by constipation, diarrhea, or alternating diarrhea and constipation —much the same sort of disturbance that is present in the irritable colon syndrome. The size, shape and consistency of the evacuated feces, except for the presence of blood, are of no diagnostic import

The situation of the pain and discomfort often does not indicate the existence of the lesion at that site of discomfort The pain may be referred and symptoms may be most prominent in a portion of the colon far removed from the neoplasm. It may [illegible] pain [illegible] ay be [illegible] be referred to the rectum when the lesion is primary in the sigmoid or cecum if there be involvement of the rectal shelf In the presence of obstructing lesions the symptoms are always expressed proximally to the lesion

In carcinoma of the *right side of the colon* there are both general and local symptoms. The symptoms of carcinoma in this region may be illustrated by reference to the predominating symptoms Of 10 patients who have carcinoma of the right side of the colon 6 will have dyspeptic symptoms; 3 will have anemia without

Diagnosis usually is made at the time of surgical exploration. Occasionally the roentgenologist can detect and correctly diagnose this tumor.

Other Benign Tumors. The incidence of other benign tumors of the gastrointestinal tract, and particularly in the colon, is insignificant as compared with the incidence of polyps and lipomas. The other benign tumors are adenomyoma (endometrioma), myoma, fibroma, angioma, lymphoma, neurofibroma, teratoma, enterogenous cysts, cholesteatoma and paraffinoma. These tumors are diagnosed by the same procedures that are employed in polyposis. Often they are discovered accidentally Dermoid cysts may be suspected by noting roentgenologic shadows of teeth or by discovering teeth and hair on proctoscopic examination.

Endometriosis of the Colon and Rectum The etiology, pathology, symptoms and diagnosis of endometriosis are considered in this text in relation to diseases of the female pelvis (see Chapter 7).

It will suffice at this point to summarize the symptoms of endometriosis as follows. The symptoms appear periodically in relation to menstruation and are (1) dysmenorrhea, (2) menorrhagia, (3) sterility, (4) rectal pain or discomfort during bowel movement, increased during menses, (5) diarrhea, worse at, or occurring only during, the menstrual period, (6) bleeding or blood-stained mucus from the rectum or the vagina, appearing with menses, disappearing thereafter, (7) rectal tenesmus and (8) pain on urination or urinary frequency. The common intermenstrual discomforts are (1) *pain in the lower part of the abdomen, pelvis,* and back and (2) dyspareunia

The diagnosis is established by biopsy of endometrial tissue, the history, and the findings on physical examination

Malignant Tumors of the Colon and Rectum. Nine of every 10 malignant tumors of the large bowel represent some variation of *adenocarcinoma* Three of every 100 cancers of the rectum and anus are epitheliomas and practically all are of the squamous *cell type Carcinoids are uncommon tumors of the colon*

Three of every 100 patients who have a malignant lesion will have a *sarcoma* somewhere in the alimentary tract. The majority of intestinal sarcomas are either lymphomatous or fibroblastic in origin

Malignant melanomas are uncommon

Pathology On the basis of their gross appearance adenocarcinomas of the colon may be roughly divided into four main types nodular, scirrhous, colloid, and papillary tumors

Adenocarcinoma of the *nodular* type often is characterized by being a sessile nodular mass which projects into the lumen and tends to encircle the colon Ulceration is common, and if the ulcer is large, the edges are characteristically indurated and nodular This tumor is hard As a result of contraction of the stroma and of inflammation set up in the tissues in and around the tumor by secondary infection in the lesion, distortions and deformities of the colon are common Chronic partial obstruction of the lumen of the rectum or colon is common The colon proximal to the tumor is often dilated or hypertrophied In more advanced obstruction the wall of the colon proximally is thinned and there are present the so-called stercoral ulcers Occasionally perforation occurs with the development of a localized abscess, peritonitis, or a fistula. In the left side of the colon the lesions tend to be smaller and harder than those of the right side

In the *scirrhous* type of adenocarcinoma due to the fibrous element of the tumor, the growth is hard and small, and tends to produce an encircling or napkin-ring type of tumor and colonic obstruction. The scirrhous lesion is found much more frequently *in the left side of the colon than elsewhere It is rare in the rectum*

Adenocarcinoma of the colloid type is uncommon in the colon

Adenocarcinoma of the colon is usually of a relatively low grade of malignancy. The grade of malignancy has been variously classified as follows:

Dukes s classification is based *on the boundaries reached in* either the rectal or the colonic tumors Rectal tumors are divided into three classes. (1) those in which the cancer is restricted to the wall of the rectum (type A, Dukes); (2) those in which

General symptoms, such as loss of weight, weakness, and anorexia, are usually not present until the patient is informed of the possible diagnosis. The tension and anxiety which ensue on knowing the nature of the illness initiate anorexia and subsequent loss of weight.

Carcinoma of the Rectum. SYMPTOMS Those who regularly inspect their stools during health report that there is a change in the character of the stool, an alteration in its regularity, and there may be grossly visible blood on the stool These are confusing symptoms, for they may have been present for years as the result of hemorrhoids, anal deformities, and anal fissures The presence of these symptoms in a middle-aged patient who has never had them previously is significant

Of less importance is a progressive change in bowel habit, because bowel habit yields easily to changes in environment and physical habits As the lesion increases in size, there is a frequent desire to defecate and a disturbing sense of incomplete evacuation, despite a normal defecation, which occasions the use of laxatives, enemas or in some instances paregoric

The pain in rectal carcinoma usually is not severe unless the anal sphincters are implicated or the tumor comes within the grasp of the sphincteric musculature. Extension of the growth into the perirectal structures causes increased severity of the pain The pain may be referred deep in the rectum, to the abdomen, back, hips, and down the thighs

Backache and sciatic distribution of the pain are often present in cancers of the rectum This type of pain may indicate an extension of the cancer along the nerves, and if this is true, surgical removal of the lesion will not relieve this pain

Constipation if present in carcinoma of the rectum becomes more severe than in those who have carcinoma of the colon

The so-called ribbon or pencil stools are of no pathognomonic significance at any time. The final form adopted by the stool is determined mainly by the caliber of the anal canal and the consistency of the feces The caliber of the anal canal which moulds soft feces may be influenced by prolapses of mucosa

EXAMINATION. Patients who have malignant tumors of the colon or rectum usually appear healthy. Some patients who have cancer of the cecum or ascending colon, even though nutrition is good, are pale and sallow Fever is uncommon.

There are usually no abnormal physical findings in the lungs Metastasis to the lungs is ordinarily a late manifestation in cancer of the colon However, when there is early metastasis to the lungs, it is a bilateral disseminated metastasis so that there are no definite physical findings

On palpation of the abdomen a mass is felt in about one third of all cases, irrespective of the situation of the growth in the bowel The mass is often hard, nodular and nontender, and it may or may not be fixed At times tumors of the cecum attain considerable size and the mass may be first discovered by the patient. When there is a lesion of the left side of the colon, in particular, obstruction is likely to be present with audible and at times visible hyperperistalsis, and abdominal distention and tympanites The mass felt in lesions of the left half of the colon is often fecal material proximal to the lesion and not the lesion itself.

Enlargement and hardening of the liver may be present without metastasis When the liver is enlarged from metastasis, often nodules can be felt. In such instances the cancer is advanced, irrespective of the smallness of the primary lesion Ascites may be present as a manifestation of abdominal carcinomatosis. A distorted, hard and fixed umbilicus as a result of metastasis is rare even in widespread abdominal carcinomatosis The inguinal lymph nodes are almost never enlarged as the result of carcinoma in the colon or rectum These nodes are often enlarged in anal, vaginal and scrotal lesions

In examination of the rectum have the patient assume the knee-chest position. The rectum is examined bimanually. A bimanual examination may reveal the pres-

visible loss of blood and with *profound weakness and loss of weight and strength*; 1 will have a palpable tumor However, it is well to know that the clinical symptoms of cancer of the colon cannot be definitely separated, depending on the segment of the colon involved

The patients who have cancer of the right half of the colon often experience a sense of fullness, a tightness, or a feeling as though gas had accumulated and could not move along in the intestine. In some there *may be mild discomfort and abdominal soreness*

The pain, if there should be such, in lesions of the right half of the colon is indefinitely localized to the right side of the periumbilical *region and the right lower* abdominal quadrant and often it is referred to the epigastrium Perforation with abscess formation and extension to the adjoining parietes results in a heightening of the pain and usually a tendency toward its localization.

About one half of the patients who have carcinoma of the right side of the colon have anorexia, bloating, belching, epigastric fullness, nausea but rarely vomiting The anorexia is often the most definite. It is described as an absolute distaste for food. It is the same sort of sensation that is experienced by those who have cancer of the stomach. Subsequent to the anorexia there are weakness in about one fourth and loss of weight in about one half of all patients

Loose bowel motions are common, in lesions of the right half of the colon and some patients have a moderately severe diarrhea. Others have normal bowel movements, or there may be alternating constipation and diarrhea The often described alternation of constipation and diarrhea is frequently associated with the use of laxatives The use of laxatives is probably prompted by the presence of abdominal discomfort A change in bowel habit is a significant symptom which often is self-invoked by medications because of abdominal discomfort.

Like constipation and diarrhea, the presence of mucus and blood in the feces is in itself of meager diagnostic importance Most persons have passed these materials often in their lifetime It is for this reason that the passage of these materials *often* does not frighten the patient The constancy of the presence of blood and mucus in [illegible] be considered as originating [illegible] *from another cause*

In carcinoma of the *left side of the colon* obstruction causes the most definite and often the only symptoms present The presence of rectal bleeding is not a *dependable symptom in lesions in the left half of the colon*

The presence of abdominal pain in lesions in the left half of the colon is variable It may accompany ulceration, perforation or obstruction and becomes more severe as one or all of these processes increase. The pain is poorly localized in the left side of the midabdomen and the lower part of the abdomen A feeling of inability to pass the flatus along may be described The expulsion of flatus often gives immediate relief. Often there is a crampy pain, frequent desire to defecate, and just preceding defecation or while straining at stool there may be a sudden intense lower abdominal pain of short duration In moderately advanced lesions a free expulsion of feces and flatus affords relief. In advanced lesions of the left side of the colon the distress becomes more intense until it is continuous torture

As a symptom of cancer of the left side of the colon constipation is more significant when it appears in one who has never been constipated than in one who has been subject to constipation *Diarrhea may be difficult to evaluate in* a patient who is accustomed to having loose bowel movements Diarrhea is rarely an early symptom of lesions of the left side of the colon

Visible *blood on* the stools is usually due to the accompanying internal hemorrhoids or to chronic anal fissure If bleeding hemorrhoids have been present for a long time, there may have been noticed a little more constancy of the rectal bleeding since the onset of the carcinoma.

the stocky, sthenic somatic type as a result of a wide flaring of rib margins and shallow dome of the diaphragm. Hepatoptosis is found in association with a generalized visceroptosis The right kidney, the stomach and the transverse colon are also displaced downward if there is hepatoptosis

Hepatoptosis exists without producing symptoms

In a great many persons in normal health, when recumbent, the lower border of the liver can often be felt at the right costal edge The position of the upper hepatic border is determined by percussion and can usually be demonstrated at the fifth intercostal space in the midclavicular line With downward displacement of the liver, the lower border can be palpated below its normal site and the upper border is found to have moved down a corresponding distance As the ptosed liver is being palpated, it can usually be rotated somewhat by the examiner's hand, indicating its abnormal mobility. When the liver is low in the abdomen, it may be possible to pass the hand along the upper hepatic surface and between the liver and the costal border. With upward pressure on its lower edge, the liver can often be forced back into a normal position, only to fall from it again when the patient arises.

Situs Inversus Viscerum. The most frequent total displacement of the liver is its transposition seen in association with the transposition of the other viscera in situs inversus viscerum In these cases the liver occupies a position in the left side of the upper part of the abdomen, a mirror image of its normal relationships to the heart, stomach and other organs, since these are similarly transposed. The heart may be transposed without the liver being affected, but transposition of the liver alone is rarely present

Acquired displacements of the liver are seen as a result of diaphragmatic hernia, kyphoscoliosis, and a number of disease conditions of the thoracic and abdominal organs.

The thoracic diseases which may cause *downward displacement* of the liver are effusion or empyema of the right pleura, emphysema, occasionally massive pericardial effusion, and subdiaphragmatic abscess

Upward displacement can result from the pressure of ascites, extreme distention of the bowel, or a large tumor which arises from any of the abdominal or pelvic organs. The liver can be pushed *forward* by retroperitoneal tumors or aneurysm Decrease in size, as in acute atrophy of the liver, permits the liver to fall away from the anterior parietes, and the space it formerly occupied is then taken by intestine

Displacement of the liver does not produce symptoms and frequently is unrecognized

Anomalies of Shape. The primitive or fetal liver is lobulated In an occasional individual the lobulations persist and as a result many lobes have been described. There may be accessory lobes (Riedel's lobe) which, if present, are usually found as finger-like projections from the portal fissure These congenital anomalies have no significance

A *Riedel's lobe* does not cause symptoms Physical examination reveals a rounded, elongated mass appended to the liver and moving with the organ on respiration The mass may extend into the right lower abdominal quadrant It is often tender on pressure There may be some difficulty in deciding, on physical examination, that the mass is a projection of the liver and not a tumor. A Riedel's lobe, if distinctly palpated, is generally found to have a sharp and somewhat firm lower edge

Such conditions as metastatic extensions of malignant lesions, tertiary syphilis, cysts and tumors cause gross structural changes in shape of the liver.

Hepatolenticular Degeneration. There are a number of neurologic syndromes which are associated with a degenerative process in the brain, involving chiefly the lenticular nucleus, and with cirrhosis of the liver.

ence of a lesion too high in the pelvis to be felt digitally. The growth may be a pedunculated polyp or a crateriform ulcer. It is hard unless it is a fungating mass. The size and shape so vary that all forms of descriptive adjectives are applicable. If the tumor is large enough to occupy a great part of the pelvis, digital examination will impart little information as to its actual size, its degree of fixation, and its attachment, if any, to other structures. The tumor may seem to possess all of these undesirable attributes and yet none of these are present It may be fixed in the pelvis *because it is too large to be moved*

In women rectovaginal examination is useful to help demarcate lesions on the anterior rectal wall

Many physicians have not felt a cancer of the rectum since their internship Experience, however, is not necessary to detect a cancer of the rectum. The unexperienced finger can detect the lesion if it be given the opportunity. It is regrettable, though, if a digital examination has not been done when the patient has sought medical advice, for more than half of the cancers of the large bowel occur in that portion which is accessible to digital and proctosigmoidoscopic examination

DIAGNOSIS The diagnosis of malignant lesions of the colon and rectum can be made definitely only after histologic examination of the tissue. Evidence disclosed by digital, endoscopic and roentgenoscopic examinations is all presumptive, but usually proves to be accurate

Carcinomas occurring in those of the younger age group tend to be more malignant than those occurring in older persons. Among women the mortality rate is lower after surgery and survival rates are better than among men The higher the grade of malignancy, the greater the likelihood of metastasis, the higher the operative mortality rate, and the lower the survival rate. In the presence of metastasis to the regional lymph nodes at the time of operation, three fourths of those surviving the operation will eventually die of cancer

The prognosis is better when the lesion is in the right half of the colon than when it is in the left half of the colon, both in patients with, and those without, lymph-node involvement When the lesions are in the transverse colon, because of the ease of infiltration of the stomach and other adjacent organs surgical treatment often is only palliative

THE LIVER

The liver is a large dome-shaped gland situated in the upper right quadrant of the abdomen which is concerned with the production of bile, conversion of most sugars into glycogen which it stores, and the metabolism of proteins and many other substances It has a double blood supply from the hepatic artery and the portal vein

The liver rises to the fourth costal interspace on the right side, to or slightly above the xiphosternal junction in the midline, and to the lower border of the fifth rib on the left side Its extremity, just beyond the apex of the heart, is at the lower border of the sixth rib Its lower border passes from this point to the eighth left cartilage, crosses the middle line about midway between the xiphoid articulation and umbilicus to the ninth right costal cartilage, and thence follows the edge of the ribs posteriorly, being about 1 inch (2.5 cm.) lower in women than in men

The outline of the liver can be approximated by percussion The upper limit of hepatic dullness in the right mammary line extends from the upper border of the sixth rib to the lower edge of the thorax In the right posterior axillary line it reaches the upper border of the eighth, and in the right scapular line, the upper border of the tenth rib. From these limits it extends downward to the edge of the ribs. The lower border can often be palpated in a liver of normal size, depending on the somatic type of the individual.

Anomalies of Position and Shape of the Liver. *Hepatoptosis.* Hepatoptosis is common in tall, thin individuals, though the liver is often palpable in persons of

determinations of fecal urobilinogen are required over a period of time in order to establish the existence of complete obstruction of the common bile duct.

After the intravenous injection of *sulfobromophthalein* (bromosulfalein) the dye is excreted by the liver almost quantitatively A test with this dye is the most satisfactory test for hepatic function in the absence of jaundice. Five milligrams of the dye per kilogram of body weight is the proper dosage. A single specimen of blood is withdrawn by venipuncture at the end of one hour The amount of dye present in the serum is determined by comparison with standardized colors in a colorimeter Retention of dye occurs in about 96 per cent of patients who give evidence of hepatic injury but who have no clinically demonstrable jaundice Occasionally a low-grade retention of the dye occurs without evidence of hepatic disease but this is rare. Marked retention (grade 3 to 4 on the basis of 1 to 4) is the rule with cirrhosis and many other chronic hepatic diseases.

The serum *alkaline phosphatase* may be increased (normal values, adults 1.5 to 4, children 5 to 14 Bodansky units per 100 ml of serum) in obstructive jaundice, while in nonobstructive jaundice the values are often normal or low Limitations are imposed on its use as an indicator of biliary obstruction, since in certain skeletal disorders, and in growing children, increased and varying levels of serum phosphatase are observed

In normal blood serum, *esterified cholesterol* comprises 50 to 70 per cent of the cholesterol In obstructive jaundice there often is an increased concentration of the total serum cholesterol while the cholesterol esters remain normal. In hepatocellular jaundice esterification may be hindered and the concentration of cholesterol esters is decreased In cirrhosis the concentration of cholesterol esters is normal Concentration of cholesterol esters less than 30 mg per 100 ml of serum is indicative of severe hepatic injury.

The sugars *galactose* and *levulose* are nearly quantitatively metabolized by the liver. Galactose is utilized apparently only very slightly if at all by other tissues In obstructive jaundice of long duration without serious injury to the hepatic cells galactose may be metabolized The most reliable information is obtained when the galactose is administered intravenously. The test is useful in the differential diagnosis of obstructive versus intrahepatic jaundice

The levulose test has not gained serious protagonists

The *hippuric acid* test is based on the ability of the liver to conjugate benzoic acid and amino-acetic acid to form hippuric acid This test is time-consuming and certain factors such as renal injury, dehydration and malnutrition affect the final results

Duodenal drainage determines the absence of bile from the duodenum by the color of the duodenal contents If bile is present, liver bile and the darker gallbladder bile (obtained after duodenal instillation of 30 ml of a 40 per cent solution of magnesium sulfate) may be obtained separately

In hepatic disease and in obstructive jaundice before there is serious injury to the hepatic cells, a decrease in supply of *vitamin K* which often is accompanied by a deficiency of blood *prothrombin* is present In the presence of obstructive jaundice there is poor absorption of *vitamin K*, and in hepatocellular jaundice there is a decrease or a suspension of prothrombin production by the liver The administration of vitamin K quickly nullifies any moderate degree of prothrombin deficiency of the blood When there is an absence of prothrombin from the blood because the liver cannot elaborate it, the administration of vitamin K is a worthless procedure

The *cephalin-cholesterol flocculation test* depends on the capacity of the blood serum to flocculate a colloidal suspension of cephalin-cholesterol complex A negative result of the test is one in which no flocculation occurs. The flocculation-inhibiting action of normal blood serum is a function of the albumin fraction of the total protein The test reveals no evidence of the degree of the hepatic injury The cephalin-cholesterol flocculation test is valuable when repeated at frequent intervals so that the trend of hepatocellular jaundice may be determined. Flocculations of grades 3 to 4 (on the basis of 1 to 4) are significant

The mechanisms responsible for the *thymol turbidity test* depend on changes in the serum lipids, the lipoprotein complexes and the gamma globulin fraction of the serum The readings vary from 0 to 4 units Readings of less than 2 are not significant In infectious hepatitis values obtained with this test are not elevated immediately after the onset of the disease Once the values of the test are elevated they remain up during convalescence It does not often give positive results in obstructive jaundice. Consequently

There is a tendency for several siblings to have such diseases, which presumably are definitely heredofamilial. The onset occurs from birth to 9 years of age, but may be deferred to 10 to 19 years of age The course is invariably progressive and often marked by exacerbations. Death usually occurs between the second and fifth years of the disease

There is difficulty in articulation, followed by dysphagia, hoarseness and weakness of the voice and, later, difficulty in mastication Eventually there is a loss of the power of speech and inability to swallow. The face is fixed in a rigid smile, the mouth is open, and saliva drools from it The appearance of the face is identical with that in severe advanced parkinsonian syndrome. Loss of emotional control and exaggeration of emotional reactions are usually present and, in the late stages of the disease, forced laughter and weeping may occur. The skeletal musculature becomes rigid In most cases a cogwheel phenomenon may be elicited, and it is evident that there is an extrapyramidal type of hypertonus A coarse and rhythmic tremor of rest is a constant sign The reflexes are often normal In the late stages of the disease it is impossible for the patients to make themselves understood Death ensues in about 3 years

The cirrhosis of the liver is latent in most instances; however, there may be acute attacks of hepatitis and cirrhosis of the liver.

The *pericorneal pigmentation* is the most important of all diagnostic manifestations. It appears as a narrow zone of greenish gray or greenish yellow overlying the outermost margin of the iris As this zone grows more and more pronounced, it slowly becomes golden The ophthalmologist views this zone with the slit lamp and records that it seems to be composed of fine golden granules lying under Descemet's membrane on the posterior surface of the cornea

The presence of a Kayser-Fleischer ring of pericorneal pigmentation and signs of cirrhosis of the liver are the main positive diagnostic findings. If these features are absent, it scarcely seems to be possible to make the diagnosis

Tests of Hepatic Function (Normal and Abnormal Values) The chief measurable excretory function of the liver is the excretion of bile and thus the bilirubin concentration of the blood Increase in serum *bilirubin* occurs when the production of bilirubin is in excess of the capacity of the liver to excrete it. In hepatitis the hepatic cells and small bile passages are injured so that the bile cannot escape and thus bilirubin accumulates in the blood stream (intrahepatic obstructive jaundice) The commoner cause of increase in serum bilirubin is obstruction of the larger bile passages (obstructive jaundice).

For the determination of the serum bilirubin the quantitative van den Bergh test is preferable to the icterus index. The van den Bergh test measures the total bilirubin present and its reaction (direct or indirect) Normal serums give the indirect reaction, and bilirubin exists in amounts varying from 0.5 to 1 0 mg per 100 ml. In the hemolytic anemias the excess of bilirubin gives an indirect reaction When the serum shows direct-reacting bilirubin, it is good proof of injury to the hepatic cells.

The degree of the increased concentration of the serum bilirubin is of some value in the differentiation of obstructive and nonobstructive jaundice. The greater concentrations of serum bilirubin are observed in acute and severe forms of hepatitis and in malignant obstruction of the common bile duct The intermediate concentrations are observed in milder degrees of hepatogenous jaundice and in the intermittent or partial obstruction of the common bile duct as by a gallstone The lower concentrations are obtained in the serum of a patient convalescing from a subsiding hepatitis or suffering from a portal cirrhosis of the liver

Bile pigment when acted on by bacteria of the colon is converted to *urobilinogen*, and a part of this is oxidized to urobilin which is passed in the feces (normal values of 50 to 300 Ehrlich units). Another part of urobilinogen is absorbed and carried to the liver by the portal circulation and partially re-excreted in the bile. The remainder of the urobilinogen passes into the general circulation and is excreted in the urine.

If the hepatic cells are injured, the part of the urobilinogen excreted in the urine is increased. When the common bile duct is obstructed no urobilinogen appears in the feces Concentrations of from 0 to 10 Ehrlich units in the feces indicate either obstruction of the common bile duct or the suppression of the secretion of bile. Repeated

jaundice as is present in disease of the right side of the heart. Jaundice is a rare complication of heart disease When it does occur as a complication of heart disease it results from hepatocellular injury from chronic passive congestion Congestion alone rarely causes jaundice unless it is of long duration. Hepatic injury due to congestion of long duration often is followed by cirrhosis Cirrhosis of the liver is common in those who have chronic failure of the right side of the heart

In the experience of Walters and Snell, an obstructive jaundice is observed in about two thirds of the patients who have jaundice. However, this group of patients was assembled from a surgical practice In general, in about one half of all instances of obstructive jaundice, the jaundice is due to obstruction of the common bile duct.

Hartman, reviewing records of 400 patients in whom treatment for jaundice was indicated, found that gallstones and associated conditions were the causative factors in about 25 per cent The icterus was due to neoplasms in about 30 per cent of this series, the great majority of such lesions being in the gallbladder, pancreas and bile ducts Benign stricture of the common duct caused the jaundice in 10 per cent of these patients

2. Infectious and toxic jaundice may arise from many and diverse agents or categories of agents which will injure the liver and produce jaundice. Many of these *agents cause an obstructive form of jaundice of the hepatocellular type, while others* produce jaundice of the hemolytic type It is for these reasons that serious objections are made against oversimplified classifications of jaundice like (McNee) the one used here. However, more elaborate classifications of jaundice may prove to be equally confusing

A convenient listing of the commoner categories of infectious and toxic agents which injure the liver and cause jaundice are

(1) The viruses of epidemic hepatitis which includes catarrhal, infectious, endemic, epidemic and possibly homologous serum jaundice, yellow fever, infectious mononucleosis and Rickettsia (a) Secondary bacterial infections in which hepatic injury is not constantly present which may occur in pneumococcic infections (lobar pneumonia) and in miscellaneous infections with organisms such as *Streptococcus pyogenes, Clostridium perfringens* and *Salmonella typhosa* and tubercle bacilli (b) Syphilis (congenital and acquired), and leptospiral infection (Weil's disease) are examples of toxic agents belonging to the Spirochaetaceae and Treponemataceae. (c) Malarial parasites injure the liver (2) The chemical toxins comprise arsenobenzol derivatives, quinoline derivatives, organic compounds and their halogenated derivatives including alcohol, ether, chloroform and carbon tetrachloride, aromatic compounds such as the phenols, benzenes, toluenes, hydrazines and their derivatives, sulfonamides and inorganic compounds, phosphorus, arsenic, lead, gold, bismuth and copper (see Chapter 19) (3) Biologic substances which include mushroom poisoning, snake venom and incompatible blood and hemolytic serums and hemorrhagic disorders of the blood (for example, sickle cell anemia). Many of these infectious conditions and substances are only rarely of clinical importance. They are all discussed in their appropriate places in this text

Cirrhosis increases the susceptibility of the liver to injurious substances

Allergy or increased susceptibility is clearly a cause of development of toxic hepatitis, especially in its relation to the toxic effects of certain drugs It may be the explanation for hepatic reactions to the arsphenamines, sulfonamides, and cinchophen

There is much evidence in recent years which indicates the susceptibility of hepatic cells to injury from dietary deficiencies and malnutrition A potent cause of hepatic disease is often the presence of a chronic generalized affection of the liver. The liver is often affected in disorders of endocrine glands (thyroid diseases), in diseases of the nervous system (lenticular degeneration), in the blood dyscrasias, in diseases of the blood-forming organs and in allergy.

it is most useful in the differential diagnosis of jaundice The thymol turbidity test is positive in a variety of diseases characterized by irritation of the reticuloendothelial cells.

The *serum gamma globulin test* is a turbidimetric test which depends on increases in gamma globulin The reaction appears to be positive in primary hepatic injury and negative in obstructive jaundice

Normal human serum has a total protein content of 6 to 8 gm. per 100 ml About two thirds of this protein is the albumin fraction and the remaining third is composed of the alpha, beta and gamma globulins The total protein content of the serum in patients who have hepatic disease may be normal, increased or decreased. Often the decrease in protein is in the albumin fraction, there may be increase in any of the globulin fractions The concentration of total protein is not altered in obstructive jaundice of short duration It may be decreased in chronic obstructive jaundice. In hepatocellular jaundice low concentrations of total protein are common

Tests of liver functional activity often are of meager diagnostic value in obstructive jaundice *when the obstruction is situated in the extrahepatic bile ducts because* these patients are rarely examined before the hepatitis incident to biliary obstruction has set in There is no measurable difference between the injury to liver cells incident to obstruction of the extrahepatic biliary ducts and that sustained from a primary hepatitis Therefore tests of liver functional activity often fail to be of any very great value in the differential diagnosis between instances of jaundice which can be relieved by surgical treatment

Tests of *liver functional activity are rarely of prognostic value in those who have* jaundice. Like tests for renal functional activity they are of little value unless taken in series with intervals of time elapsing between tests It is the trend of the values given by the succeeding tests which gives the greatest information for both diagnosis and prognosis

Jaundice. THE CLASSIFICATION OF JAUNDICE. Some sort of classification of jaundice is necessary for descriptive purposes Because of its simplicity and wide *applicability McNee's classification is useful and frequently employed* Accordingly, jaundice is divided into three categories (1) obstructive, (2) infectious and toxic and (3) hemolytic (see Chapter 12)

1. In obstructive jaundice the mechanism of the icterus is primarily some interference with the flow of bile This may be due to a lesion such as carcinoma of the pancreas, or to mechanical interference with the extrahepatic bile passages, such as a stone, but it may be a process that causes infiltration of the periportal spaces and thus produces a hindrance to the flow of bile anywhere along its course, beginning within the hepatic lobules In biliary obstruction caused by a carcinoma of the pancreas, for instance, there is within a short period of time injury of the hepatic cells

Obstructive jaundice may be produced by many different intrinsic and extrinsic lesions of the bile ducts. The great variety of these is indicated in the following *enumeration:*

Intrinsic obstructive lesions of bile ducts comprise gallstones, inflammatory exudate, and parasites Intrinsic lesions which may arise in the walls of *the bile ducts* comprise inflammatory changes, strictures, neoplasm, and spasms of the duct or of the sphincter of Oddi

Obstructive jaundice as a part of pulmonary disease may occur as *a complication of pneumonia* (see Catarrhal Jaundice, p 1026). Jaundice often occurs in the presence of extensive *pulmonary infarction due to embolism* or to thrombosis secondary to a *slowed* circulation In instances of slowed circulation, hemolysis is usually the cause of *the jaundice*

[illegible] caused by the pressure [illegible], condition there is injury to hepatic [illegible]

Hepatocellular disease may be manifested as an intrinsic form of obstructive

jaundice as is present in disease of the right side of the heart. Jaundice is a rare complication of heart disease When it does occur as a complication of heart disease it results from hepatocellular injury from chronic passive congestion Congestion alone rarely causes jaundice unless it is of long duration Hepatic injury due to congestion of long duration often is followed by cirrhosis. Cirrhosis of the liver is common in those who have chronic failure of the right side of the heart.

In the experience of Walters and Snell, an obstructive jaundice is observed in about two thirds of the patients who have jaundice However, this group of patients was assembled from a surgical practice. In general, in about one half of all instances of obstructive jaundice, the jaundice is due to obstruction of the common bile duct

Hartman, reviewing records of 400 patients in whom treatment for jaundice was indicated, found that gallstones and associated conditions were the causative factors in about 25 per cent The icterus was due to neoplasms in about 30 per cent of this series, the great majority of such lesions being in the gallbladder, pancreas and bile ducts Benign stricture of the common duct caused the jaundice in 10 per cent of these patients

2. Infectious and toxic jaundice may arise from many and diverse agents or categories of agents which will injure the liver and produce jaundice Many of these agents cause an obstructive form of jaundice of the hepatocellular type, while others produce jaundice of the hemolytic type It is for these reasons that serious objections are made against oversimplified classifications of jaundice like (McNee) the one used here. However, more elaborate classifications of jaundice may prove to be equally confusing

A convenient listing of the commoner categories of infectious and toxic agents which injure the liver and cause jaundice are

(1) The viruses of epidemic hepatitis which includes catarrhal, infectious, endemic, epidemic and possibly homologous serum jaundice, yellow fever, infectious mononucleosis and Rickettsia (a) Secondary bacterial infections in which hepatic injury is not constantly present which may occur in pneumococcic infections (lobar pneumonia) and in miscellaneous infections with organisms such as *Streptococcus pyogenes, Clostridium perfringens* and *Salmonella typhosa* and tubercle bacilli (b) Syphilis (congenital and acquired), and leptospiral infection (Weil's disease) are examples of toxic agents belonging to the Spirochaetaceae and Treponemataceae. (c) Malarial parasites injure the liver (2) The chemical toxins comprise arsenobenzol derivatives, quinoline derivatives, organic compounds and their halogenated derivatives including alcohol, ether, chloroform and carbon tetrachloride; aromatic compounds such as the phenols, benzenes, toluenes, hydrazines and their derivatives; sulfonamides and inorganic compounds, phosphorus, arsenic, lead, gold, bismuth and copper (see Chapter 19) (3) Biologic substances which include mushroom poisoning, snake venom and incompatible blood and hemolytic serums and hemorrhagic disorders of the blood (for example, sickle cell anemia) Many of these infectious conditions and substances are only rarely of clinical importance. They are all discussed in their appropriate places in this text

Cirrhosis increases the susceptibility of the liver to injurious substances

Allergy or increased susceptibility is clearly a cause of development of toxic hepatitis, especially in its relation to the toxic effects of certain drugs It may be the explanation for hepatic reactions to the arsphenamines, sulfonamides, and cinchophen

There is much evidence in recent years which indicates the susceptibility of hepatic cells to injury from dietary deficiencies and malnutrition A potent cause of hepatic disease is often the presence of a chronic generalized affection of the liver The liver is often affected in disorders of endocrine glands (thyroid diseases), in diseases of the nervous system (lenticular degeneration), in the blood dyscrasias, in diseases of the blood-forming organs and in allergy.

An excessive protein destruction may occur during prolonged fevers. Inadequacy of glycogen and deficiency of protein both render the liver more susceptible to the action of toxic substances. Likewise a deficiency of vitamins, specifically of the vitamin B fractions, may be important as an etiologic adjunct in the development of hepatic disease.

3. The jaundice in hemolytic icterus is due to an excessive destruction of the erythrocytes. An excessive amount of bilirubin is produced which cannot be excreted by the liver as fast as it is formed. Hemolytic icterus is not a disease of the liver. It is a blood dyscrasia or due to a hemolytic agent circulating in the blood.

Hemolytic icterus may be first brought to the attention of the physician by a patient's reaction to the van den Bergh test There is an increased bilirubin, a (delayed) indirect reaction (see Chapter 12).

In summary it is emphasized that the foregoing classification of jaundice is inadequate The lines of separation of the categories of toxic agents and their exact action on the liver and bile ducts cannot always be drawn The separation of the two groups of obstructive jaundice, namely, (1) the types which arise in the hepatic parenchyma which are not relieved by surgical treatment from (2) the forms of obstructive jaundice due to obstructions of the flow of bile into the intestine and which are relieved, is important

In case of stone in the common duct, in which complete biliary obstruction does not persist for long periods, the degree of distention may not be great, and injury to the hepatic cells may be minimal When malignant disease is responsible for the obstruction it is permanent, until relieved by the surgeon The continued excretion of bile by the hepatic cells further increases pressure within the biliary system, and the smaller canaliculi overdistend and rupture Extravasated pigment enters the lymph and blood spaces of the hepatic lobules, and finally from here passes into the general circulation, thus causing *manifest jaundice*

The degenerative changes which occur in hepatic cells during the course of biliary obstruction tend to disappear when the obstruction is relieved Rarely does mechanical obstruction produce permanent changes in the liver of a sufficient degree to cause cirrhosis However, a form of biliary cirrhosis due to obstruction does occur.

The *absence of bile and of bile salts from the intestines* produces changes in the digestion and absorption of fat. The caloric value of fat is lost The manifestations of loss of the fat-soluble vitamins, A, D and K, may be observed In the adult the loss of vitamins A and D does not produce manifestations of a degree of severity that such a loss may produce in children The loss of vitamin K is an important loss manifested by a prolonged prothrombin time of the blood and hemorrhagic tendencies.

Bile and the components of bile accumulate in the blood The bile stains all of the tissues including the skin and excretions from the body such as the urine and the sweat. The concentrations of the components of the bile, for instance, the cholesterol, phosphatase and bile acids, also are increased The accumulation of these substances in the blood increases the injury of the hepatic parenchyma and destroys the general health

SYMPTOMS. The patient complains of a yellow color which commences in the whites of the eyes and then appears in the skin. As the jaundice develops, nausea, perhaps anorexia and loss of body weight are present. Since jaundice itself is a symptom the attending discomforts are those of the prevailing disease.

The evidence on which it has been concluded that bile salts produce bradycardia and pruritus is incomplete and somewhat faulty. Bradycardia and pruritus are not due to the presence of excessive amounts of bile in the blood, for these are never present in hemolytic jaundice, a condition also attended by excess of bile in the blood

The hepatic cells are adversely affected by the changes which follow biliary

obstruction The degree of hepatic dysfunction as evidenced by tests of hepatic functional activity is somewhat proportionate to the duration and degree of obstruction

As biliary obstruction develops, there are changes in the color of the stool and the urine which in retrospect have been observed by the patient before the discoloration of the skin was evident When gallstones are present, complete obstruction may be transient, so that the character of the bowel movements may be unchanged. With prolonged biliary obstruction the feces are free of bile and are of a light color (putty colored) and remain so for the duration of the obstruction

The urine becomes discolored to deep brownish red in proportion to the amount of bile it contains Intermittent changes in the color of the urine often indicate intermittent obstruction such as that caused by a stone

Examination. The degree of jaundice observed and the size of the liver as revealed by palpation are of relatively little value in regard to the etiology or the diagnosis of obstructive jaundice

The spleen is rarely enlarged early in the course of obstructive jaundice. If the spleen is palpable, the jaundice present is likely to be hemolytic or hepatic in origin.

The essential demonstration to be made by observations and laboratory examinations in obstructive jaundice is the failure of bile to enter the intestinal tract. Absence of bile can be approximately determined by visual examination of the feces The so-called clay-colored stool often indicates the absence of bile In instances in which it is necessary to determine the presence or absence of bile in the intestines this can be accomplished by chemical analysis of the feces for bile (Gmelin's test) or by duodenal intubation Also characteristic of complete biliary obstruction is the disappearance of urobilinogen from the urine and the stool

The most accurate method for measuring the degree of jaundice and observing its course is by repeated determinations of the serum bilirubin concentration by means of the quantitative van den Bergh test An increase in the bilirubin content of the blood begins almost immediately after the onset of obstruction of the common bile duct The speed of the rise and the concentration reached depend on the degree of the obstruction Simultaneous with the rise in serum bilirubin, and often paralleling it, there are usually increases in the total values for blood cholesterol and blood phosphatase.

The most serious blood chemical finding in those who have obstructive jaundice is hypoprothrombinemia, which is an important cause of hemorrhages in this condition Hypoprothrombinemia originates from the absence of bile acids from the intestine and the consequent failure of the intestines to absorb fat and the fat-soluble vitamins, especially vitamin K, needed by the liver to synthesize prothrombin In prolonged biliary obstruction the concentration of prothrombin in the blood decreases sufficiently to permit serious hemorrhages to occur, particularly after surgical operation

The value for prothrombin cannot be determined directly by chemical methods The amount present in the blood can be measured by determining the capacity of the blood to form thrombin and initiate the clotting process.

Quick perfected a one-stage method which utilizes the principle that the coagulation time of blood or plasma is a direct measure of the concentration of prothrombin, provided the other clotting factors, thromboplastin, calcium and fibrinogen, are constant For the purpose of this test, the fibrinogen is considered to be a constant factor, exerting little influence on the rate of coagulation

Consensus is that the simplified one-stage method devised by Quick is satisfactory for the detection of pronounced degrees of hypoprothrombinemia and for the clinical control of vitamin K therapy The normal coagulation time by this method is 17 to 20 seconds

Diagnosis of Jaundice. The differentiation of the obstructive form of jaundice from the hemolytic form is not often a problem Hemolytic icterus is rare, and when

of the congenital variety, it is usually characterized by such distinct clinical and hematologic features as to make its recognition relatively easy. Obstructive jaundice and that due to hepatocellular disease, however, are encountered with about equal frequency The general problem in the diagnosis of jaundice is in reality the differentiation of these two varieties from each other The differentiation is not ordinarily difficult.

In 4 of every 5 cases it is possible to determine at the bedside the type of jaundice from which a patient is suffering. The 1 remaining patient of every 5 may require the utilization of clinical judgment and observations and laboratory procedures over a period of time in order to arrive at a correct diagnosis.

The treatment of obstructive jaundice is fundamentally surgical

Cholemic Nephrosis. Renal insufficiency may result from or be associated with jaundice and hepatic disease. The renal injury that is associated with long-standing obstructive jaundice consists largely of degenerative changes in the epithelium of the renal tubules Whether these changes are produced by the bile substances which the kidneys are forced to excrete or by toxic materials which would normally be destroyed, is not known. The urine is dark in color and heavy with albumin.

Epidemic Hepatitis *(Infectious Jaundice)* The term catarrhal jaundice which formerly was widely used should be employed only when there is cholangitis due to bacterial invasion of the bile ducts such as may occur during the course of infections by the pneumococcus. Terms now preferable to designate the condition formerly called catarrhal jaundice are epidemic jaundice and infective jaundice or infectious jaundice because of the frequent occurrence of the icterus in mild epidemic form. The term epidemic hepatitis is preferable for viral hepatitis or to designate viral jaundice which seems to be the commonest cause of jaundice in patients in the younger age groups

ETIOLOGY Epidemic hepatitis, a disease due to a filtrable virus, has been transmitted to human volunteers The disease is specific for man Attempts to transmit the infection to guinea pigs, white mice, rats, rabbits, hamsters, kittens, gerbils, baboons, chimpanzees, and a variety of monkeys, all have failed

The virus has been found in both the blood and the feces of patients suffering from epidemic hepatitis Epidemics borne by water, milk and food have been described Direct spread by person-to-person contact seems likely, although the experimental evidence indicates that transmission by the intestinal-oral circuit is the most important.

In homologous serum jaundice also of viral origin, the virus is found only in the blood during the incubation period and in the preicteric and icteric phases of the disease

One attack of the infection confers immunity in either epidemic jaundice or homologous serum jaundice and, indeed, these two seem to be the same disease.

PATHOLOGY. The important features in the natural history and pathology of the disease have been described by several observers Lucké described, essentially as follows, his observations based on more than 300 cases in which death occurred, a series of cases, studied through biopsies, in which the disease was not fatal; and a group in which recovery from hepatitis was complete

Biopsies of hepatic tissue reveal that the lesions in nonfatal instances of the disease resemble those of fatal instances in kind but in a milder degree. There are acute necrosis and autolysis of the hepatic cells, and some of the cells contain inclusion bodies which take an acid stain. The damage is quickly repaired, and histologically the lesions cannot be distinguished from those of inoculation hepatitis Furthermore, the changes in sporadic and epidemic cases cannot be distinguished from one another

Postmortem examination of the liver, in cases in which death has occurred from accident or from unrelated disease subsequent to recovery from infectious hepatitis, reveals rapid regeneration.

Residual damage or progressive pathologic change is not observed in cases in which examination is made from 2 months to 3 years after an attack, nor is there evidence of progression to cirrhosis in these cases.

The hepatic lesions may be extensive before the onset of symptoms The degree of

jaundice is not correlated with the severity of the disease. The jaundice is only partly explained by obstruction of biliary canaliculi by bile casts.

The lesions found in cases of hyperacute epidemic hepatitis, namely, those in which the disease is fatal in 2 to 10 days after the clinical onset, have been described by Wood and compared with those in acute homologous serum hepatitis. On the second day the liver cells are already swollen and detached from one another, and by the tenth day they have autolyzed and the debris has been removed Inflammation is most evident in the early stages Wood has emphasized the similarity of the changes to those of acute yellow atrophy. He has expressed the belief that the acute course and high mortality rate in the group (10 per cent) might be explained by the previous poor nutritional state of the patients consequent to war wounds of long standing

Despite the close similarity of the lesions in homologous serum hepatitis and epidemic hepatitis, emphasized by both Lucké and Wood, it appeared from the work of Neefe, Stokes and Gellis that two different agents were involved In their experiments, 6 human volunteers, after recovery from homologous serum jaundice, were immune to reinoculation of the agent, but 5 had jaundice after an inoculation with material containing the agent of infectious hepatitis

Epidemic hepatitis occurs most frequently in persons less than 30 years of age. Occasionally the disease occurs in persons of 50 years or more, particularly during epidemics.

Small epidemics occur in families, institutions, and schools The disease appears most commonly as isolated and sporadic cases

Symptoms A prodromal period of 2 to 7 days is common During this time the symptoms usually present are headache, malaise, anorexia, constipation or diarrhea, nausea and vomiting Mild abdominal pains are frequently present, but in rare instances rather severe pain may occur in the right upper quadrant of the abdomen. Symptoms in the upper part of the respiratory tract are not unusual, and there may also be generalized aches and pain similar to those that occur during an attack of grippe During the prodromal period there may be fever with temperatures ranging as high as 101 F (38 3 C). These symptoms frequently subside in the course of a few days and there may be a relatively symptom-free short period just before icterus is manifested In other instances the symptoms increase in severity at the time that jaundice appears and then slowly subside.

The jaundice begins gradually, if at all, for many who have this disease are never jaundiced, although in an occasional patient the icterus may seem to come on acutely, sometimes developing overnight. The onset of icterus is frequently forecast by a darkening of the color of the urine followed by an icteric tint of the scleras and face Once it begins, jaundice usually increases rapidly in intensity The time of occurrence of a maximal degree of icterus and the duration and severity of the discoloration also vary widely The duration of the jaundice is usually measured in days; in an occasional instance this may extend into weeks or, rarely, months.

Symptoms alleged to be associated with icterus, such as bradycardia and pruritus, occur with variable frequency in epidemic hepatitis and are no more important than the amount of discomfort they give the patient

Examination. During the course of epidemic hepatitis the liver often increases appreciably in size, its edge usually being somewhat rounded and slightly tender In protracted disease the liver may seem firm With improvement, there is a gradual decrease in hepatic size Very rapid decrease in the size of the liver, as measured by percussion of the upper and lower borders, is an ominous sign, particularly if the patient becomes more icteric and more prostrated In such a case the development of acute yellow atrophy is suspected Splenic enlargement of moderate degree is observed in from one third to one half of the patients. Since this ocurs only rarely in obstructive jaundice, discovery that the spleen is enlarged is a sign of diagnostic importance

The number of blood cells may be within the normal range, or there may be mild leukopenia with relative lymphocytosis.

Determination of the serum bilirubin concentration furnishes the only accurate method for measuring the intensity of the icterus. The appearance of the urine, however, does afford a simple method of following the course of the disease, since a decrease in the discoloration of the urine is frequently one of the first signs of improvement. Only rarely are stools completely acholic during the course of an attack of epidemic hepatitis, although the amount of bile pigment they contain is commonly reduced. In those instances in which the stools have been acholic, a reappearance of bile-stained stools is a sign of improvement The significant laboratory findings in epidemic hepatitis are those revealed by the various liver function tests It does not matter which of the many that may be employed are used. The proviso is that they must be correctly interpreted If the tests are performed early in the course of the disease, within the first two weeks in the average case, definite evidence of hepatic cell disturbance is usually noted The galactose tolerance test has been particularly valuable for this purpose and the reaction has been positive in about 80 per cent of cases of epidemic hepatitis if the test is performed during the acute stages. Other tests, such as the hippuric acid test and the cephalin-cholesterol flocculation, thymol turbidity, zinc sulfate tests, and others also usually give positive results in the early phases of epidemic hepatitis

DIAGNOSIS A patient who is young and who gives a history of the onset of jaundice after prodromal gastrointestinal symptoms or symptoms simulating grippe, without a history of contact with hepatotoxic drugs, usually has epidemic hepatitis The liver and the spleen are often enlarged Diagnostic tests of liver function usually give evidence of hepatic cell dysfunction. The subsequent rapid improvement that commonly follows the acute onset is also rather characteristic and aids in confirming the diagnosis

Differential diagnosis requires primarily the exclusion of the possibility of jaundice due to mechanical biliary obstruction This type of jaundice is rare in persons of the age of the average patient who has epidemic hepatitis but must be considered in those who are in or beyond middle life The two most important types of obstructive icterus are those due to cholelithiasis and those due to carcinoma of the head of the pancreas Differentiation of these two types of obstructive jaundice from catarrhal icterus is usually fairly easy clinically. When difficulties are encountered, these often arise from failure of the gallstones to cause pain, the occurrence of pancreatic malignant disease in a young patient and the development of epidemic hepatitis in one who is older than the usual patient who has this type of jaundice. Those who have the disease without jaundice may not be detected unless severe liver injury is sustained.

PROGNOSIS. Lucké quoted mortality rates of various epidemics of hepatitis, particularly those occurring among military personnel These range from 0.13 to 0 44 per cent. He was able to examine the livers of 14 patients who had recovered from attacks of epidemic jaundice Lucké concluded that complete restoration of the hepatic parenchyma occurs in nonfatal hepatitis and considered this a natural consequence of the acute and noncontinuous injury to the hepatic cells.

The prognosis of epidemic hepatitis is good, as stated Occasionally, however, there is a transition from what at the onset seemed to be an ordinary example of the usually mild disease to a process of great severity which may end fatally. Termination of epidemic hepatitis in acute hepatic atrophy is further evidence of the underlying injury to hepatic cells that is present in some cases. Yellow atrophy develops only rarely, because the causative factors are not ordinarily severe enough to over-
[illegible]r.

[illegible] mologous serum hepatitis
[illegible]ns of measles convalescent

serum had been given This observation was followed by reports of jaundice which developed subsequent to the administration of vaccines containing human serum The disease was widely studied when it appeared among military personnel who had received yellow fever vaccine containing human serum as a diluent.

Homologous serum hepatitis is a viral disease.

The very nature of viral hepatitis *precludes the possibility of determining* whether the disease has been transmitted by blood or its derivatives and thus called homologous serum hepatitis, or whether it is due to acute infectious hepatitis.

It is noteworthy that about 26 per cent of the patients studied by Ratnoff and Mirick received injections of arsenicals or other medicaments and did not receive blood or a derivative This substantiates the observation that the virus may be transmitted from a known patient or a carrier by skin puncture with an improperly sterilized instrument Instruments contaminated with virus require heat sterilization by autoclave or by boiling in water for 15 minutes Hence, when viral hepatitis appears after transfusion of blood or its products, it is difficult to establish whether blood or another avenue of infection is responsible

Because whole blood is used more frequently than plasma, whole blood transfusion is responsible for more cases of homologous serum hepatitis than plasma transfusion From 11 to 12 per cent of patients cited by Ratnoff and Mirick had received only blood, 2 to 3 per cent received both plasma and blood, 2 patients received plasma alone; 1 patient received icterogenic yellow fever vaccine, and 1 patient received human globulin Other investigators report a 0 2 to 0 4 per cent incidence of hepatitis following whole blood transfusion The percentage incidence is higher with plasma than with whole blood because transfused plasma is usually derived from a pool of many samples; one infected sample, by contaminating a whole pool, endangers all recipients. One report presented an incidence of 3 4 per cent possible and 2 1 per cent probable hepatitis following transfusion with unsterilized plasma Another report recorded an incidence of *5 per cent*

Ultraviolet irradiation will inactivate the virus of hepatitis in icterogenic serum A method of sterilization of serum and plasma has been approved as satisfactory by The National Institutes of Health However, it has been shown that this method can fail when large quantities of plasma are being processed

The symptoms are similar to those of infectious hepatitis, but in general they are somewhat less severe.

The findings on examination are identical with those of epidemic hepatitis

The history of having received human blood or products of human blood from 60 to 180 days prior to onset of the illness is diagnostic

Recovery is expected Improvement begins 1 to 2 weeks after the jaundice reaches its peak Early mortality rate is about 0 2 per cent. Massive necrosis with rapid hepatic insufficiency may suddenly occur during convalescence The cirrhosis which may follow epidemic hepatitis is either a nodular cirrhosis (Mallory) or rarely a biliary cirrhosis

Toxic Jaundice. The toxic substances themselves may cause direct injury to the hepatic cells or may act as a form of allergy or hypersusceptibility. Chemicals such as hydrazine derivatives, toluenediamine, arsine and hemolytic serums may injure the liver from the hemolysis produced in the blood (see Diseases due to Chemical Agents, Chapter 19) Direct injury to the hepatic cells is the mechanism of action of such substances as phosphorus, various dyes, and fat-dissolving chemicals such as carbon tetrachloride, chloroform and others of the halogenated hydrocarbons. The mechanism by which arsenicals and sulfonamides inflict injury on the liver is unknown (see Chapter 19)

Arsenical Hepatitis. The hepatitis which may follow the arsenical therapy of syphilis was formerly among the most important hepatocellular injuries of chemical origin. That the jaundice is produced by some direct action of the drug on the liver seems most likely.

In arsenical hepatitis there are degenerative changes of the parenchyma which vary from cloudy swelling and edema to actual necrosis. This may be focal or diffuse and, if of a sufficient degree, may warrant a diagnosis of acute yellow atrophy. In some cases pericholangitis and the deposition of bile thrombi in the smaller bile passages occur, producing an intrahepatic form of obstructive jaundice which can be clinically recognized by the absence of evidences of hepatic dysfunction ordinarily considered characteristic of degeneration of hepatic cells.

SYMPTOMS. Jaundice may follow very small dosage of the arsenical drugs administered by mouth or intravenously. After the first dose or after only a few doses the toxic effects on the liver are manifested by jaundice.

Two forms of jaundice follow treatment with arsenicals, an early and a late form The early type may follow within 1 to 15 days after an injection. The late variety may not appear until 4 or 5 months after the last arsenical treatment has been given.

Icterus may occur alone or may be preceded by fever, chill, general malaise, nausea and vomiting and, in some instances, pain in the right upper abdominal quadrant In the delayed type of paratherapeutic jaundice toxic symptoms are less frequent than in the early variety. In both forms the icterus reaches its peak in about a week Then there may or may not be prostration and malaise. Itching is occasionally severe. Pronounced loss of body weight may ensue

The icterus persists for variable periods. The majority of patients recover completely within 4 to 6 weeks. Systemic manifestations usually subside long before the jaundice disappears, although pronounced asthenia may remain for long periods.

EXAMINATION. There is hepatic enlargement in more than one half of the cases Splenic enlargement may be present in 1 of every 10 cases. Ascites may develop during the course of the icterus and gradually disappear as recovery takes place

There are no characteristic blood findings which would aid in the diagnosis of postarsphenamine jaundice

In the majority of cases of paratherapeutic icterus the tests of hepatic function indicate the presence of acute injury of the hepatic cells

DIAGNOSIS. If arsenicals have been administered and there is found no other cause for the icterus, it is assumed that arsenic is the etiologic agent. Arsenical therapy can be considered the possible cause of icterus occurring as long as 6 months after therapy has been given

The majority of patients who have arsenical hepatitis make a complete clinical recovery in a few weeks Acute yellow atrophy may ensue in a few instances

Jaundice Following the Use of Sulfonamides. Jaundice which follows the administration of one of the drugs of the sulfonamide group may be produced as a result of an acute hemolytic crisis and profound anemia, or may be due to direct toxic injury to the liver and the development of hepatitis or both.

The basis for the development of hepatic dysfunction and clinical hepatitis subsequent to the use of sulfonamides is not clear The presence of antecedent disease of the liver is not often responsible In some instances specific drug hypersensitivity seems to have been the responsible factor

The pathologic changes induced in the liver by sulfonamides are primarily degenerative processes The characteristic feature is an extensive focal necrosis In some instances this has been sufficiently extensive to cause changes resembling those of acute yellow atrophy.

The amount of sulfonamide which will cause hepatitis varies considerably. Hepatitis may follow one dose or many doses.

Unlike the icterus which follows the acute hemolytic anemia caused by sulfonamides, jaundice due to hepatitis does not occur early in the course of the chemotherapy. Icterus may not ensue until several days or weeks have passed after the discontinuance of administration of the sulfonamide

SYMPTOMS. The onset of the jaundice is usually insidious and not preceded by other symptoms. However, chills and fever and systemic symptoms of varying

severity may occ... gradually increases for a week or 10 ... ic enlargement is generally ...

Tests of hepatic function usually reveal evidence of dysfunction of the liver.

DIAGNOSIS. The onset of jaundice while one of the sulfonamide drugs is being administered, or shortly thereafter, is the chief clue to the nature of its origin. The presence of definite hepatic dysfunction and the absence of anemia or of evidence of hemolysis serve to exclude the possibility of acute hemolytic anemia.

The prognosis of sulfonamide hepatitis varies considerably with the severity of the poison In general the prognosis is favorable. It is unwise to administer sulfonamides to patients who recover from the hepatitis.

Cinchophen Hepatitis. In recent years the use of cinchophen has decreased sharply, with a corresponding reduction in the number of cases of toxic hepatitis which it produced

The toxic effects of cinchophen have been classified by Parsons and Harding as follows (1) *cutaneous manifestations* such as pruritus, angioneurotic edema, urticaria, and macular and papular rashes, (2) *anaphylactoid reactions* characterized by neurocirculatory disturbances; (3) *gastrointestinal disturbances,* including ulcers of the mouth, heartburn, nausea, vomiting and diarrhea; and (4) *hepatic involvement* as indicated by the appearance of jaundice, which varies in degree and may range from transitory icterus to acute yellow atrophy.

Beaver and Robertson described the lesion of cinchophen hepatitis as acute atrophy with profuse acute parenchymatous degeneration and necrosis

Anorexia, nausea and vomiting, and pruritus may precede the jaundice. However, the jaundice commonly begins insidiously, and is usually painless, with or without fever. The icterus reaches its maximum in the course of a few days. In those killed by cinchophen, the icterus gradually increases in intensity until death occurs. In the nonfatal instances the jaundice lasts for a variable length of time; in some for more than 2 months There may be hemorrhage from esophageal varices When the condition is fatal, progressive stupor, coma and delirium may be expected. The terminal rise in temperature so characteristic of "liver death" is frequent

On examination an ascites may be present The size of the liver varies considerably The liver may be enlarged in those patients who are not seriously ill The spleen is often enlarged in the prolonged illnesses

Diagnosis depends on knowledge that the patient is taking the drug or has had it The clinical features of cinchophen hepatitis are indistinguishable from those produced by other forms of toxic or infectious injury to the liver

A poor prognosis is indicated by persistence and increasing intensity of the jaundice, the development of mental symptoms, the appearance of hemorrhagic phenomena, oliguria, hyperazotemia and increasing hepatic dysfunction as indicated by results of liver function tests One half of those who have cinchophen jaundice die.

Acute Yellow Atrophy of the Liver. Numerous terms, including acute necrosis and subacute necrosis of the liver, have been used to designate the disease states characterized by destruction of the hepatic cells

Acute yellow atrophy of the liver is characterized by jaundice, decrease in the size of the liver, hemorrhages, and nervous symptoms which usually terminate in coma and death It is a rare disease of early adult life.

The consensus is that all of the various noxious agents such as drugs, metabolic poisons, and infections which under certain conditions produce only a mild hepatitis, might, on occasion, induce the severe changes which terminate in acute yellow atrophy.

In an editorial in the Journal of the American Medical Association it was pointed out that the incidence curve of acute yellow atrophy of the liver has presented three peaks during the last three decades. The first period of excessive frequency was from 1918 to approximately 1924, inclusive, that is, the years immediately following World

War I. The second peak occurred from 1928 to 1934, inclusive, and the third abnormal increase in such cases was recorded during World War II and immediately after. A different etiologic factor has been advanced for each of these three epidemic-like appearances of acute yellow atrophy An accentuated toxic effect of arsphenamines on the liver because of a lowered resistance of this organ resulting from prolonged insufficient nutrition was blamed for the first wave of acute yellow atrophy, mainly recorded from Germany and Austria; starvation had been prevalent there during the last years of World War I and the years thereafter. The second increase in reports on acute yellow atrophy coincided with publications on the specific hepatotoxic action of cinchophen preparations, these had been used to an increasing degree since 1912 for the control of various painful conditions The last peak was related to the occurrence of virus-conditioned infectious hepatitis among the combatants of the various nations fighting in the Mediterranean theater of war, although smaller local epidemics were recorded from other parts of Europe and America during this period.

A critical analysis of the evidence on which the etiologic claims as to the hepatotoxic role of arsenicals and cinchophen were based throws serious doubts, according to the editorial, on the validity of these explanations. Postarsphenamine jaundice, postcinchophen jaundice and infectious jaundice are clinically, biochemically and pathologically indistinguishable from one another In regard to the hepatotoxic action of arsphenamines it was noted at that time that an appreciable number of patients with acute yellow atrophy who were observed after World War I had not received injections of these drugs

Snapper reported that arsphenamine treatment given to the generally undernourished North Chinese did not elicit at any time an increased incidence of acute yellow atrophy, refuting thereby the claim that the combination of lowered hepatic resistance through starvation and a chemotoxic action of arsenicals on the liver was responsible for the temporary numerical rise in the incidence of acute yellow atrophy during the years following World War I A direct, nonallergic hepatotoxic action of arsphenamines in these cases is improbable, since the amounts of these drugs normally used in the treatment of syphilis are definitely below a hepatotoxic level Recent observations on the transfer of infectious hepatitis, which may lead to acute yellow atrophy, have shown that improperly sterilized needles and syringes may play an important part in this respect The introduction of infected homologous serum may occur not only with the injection of human plasma, but also accidentally, during routine venipuncture with syringe and needle for blood samples for blood sugar determinations or similar tests, or during routine intravenous injections of arsphenamine, pentothal sodium, penicillin and other drugs The observations reported in this respect by Marshall are particularly instructive, according to the American Medical Association editorial He observed in 50 per cent of the patients receiving arsenicals intravenously the development of jaundice on about the hundredth day after the first injection, when special precautions were not applied to the sterilization of the needles and syringes There was no case of jaundice after a special new syringe for individual use was boiled before and after injection Inasmuch as infectious hepatitis was observed among the soldiers participating in World War I, the distinct likelihood exists that the transitory increase of acute yellow atrophy in the postwar period was essentially not of arsenotoxic origin but of infectious nature.

There exists now little definite evidence favoring the concept that the second wave of cases of acute hepatitis resulted from a hepatotoxic action of cinchophen. Apparently cinchophen and its derivatives do not exert a direct, nonallergic hepatotoxic effect in various species even when given in lethal doses or in toxic doses over a long period There were for some years cinchophen preparations on the market which were given intravenously Yellow atrophy was not seen among the patients of several institutions in which cinchophen preparations were administered routinely and over a considerable number of years; several physicians each observed more than 1 case of yellow atrophy despite a restricted use of the drugs in their private practice. There is also no plausible explanation for the fact that the hepatic complications allegedly caused by cinchophen made their first appearance some 15 years after the introduction of the drug and that few cases of cinchophen hepatitis have been reported during the last 8 years despite a considerable continued use of cinchophen during this time in this and other countries

During the last 20 years similar claims concerning the cause of acute yellow atrophy

of the liver have been made for a number of other therapeutic chemicals. The evidence presented suggests that the existence of an infectious hepatitis represents for at least some of them a distinct possibility and should be kept in mind for future occurrences of this type

PATHOLOGY. On gross examination the liver is diminished in size, in some cases to even less than half the normal The color is yellow or yellow streaked with red The liver is soft and is easily torn

When the liver is cut, its softness is even more apparent. The cut surface is often of the same yellow or mingled red and yellow color as that of the intact surface. Involvement is not uniform and the disease process may vary considerably in different portions of the liver.

The spleen is usually enlarged Degenerative changes may be present in the pancreas, and profuse hemorrhages occur throughout the gastrointestinal tract. The renal lesions consist of granular and fatty degeneration in the convoluted portions of the tubules. The glomeruli are normal.

SYMPTOMS The symptoms before the appearance of jaundice consist of anorexia, nausea, vague abdominal discomfort, vomiting and diarrhea There is a low fever, weakness, headaches and generalized aches and pains

The jaundice of acute yellow atrophy commences insidiously about 2 weeks after the onset of the preicteric symptoms With the developing jaundice there is an increase in the gastrointestinal disturbances Malaise, anorexia and prostration become totally incapacitating Often there is pain in the hepatic region There soon are severe headaches, photophobia, and restlessness, and a tendency to delirium and convulsions ensues Urinary and fecal incontinence often appear. As the acute hepatic atrophy advances, there is vomiting of blood and bleeding from the bowel. There may be vaginal bleeding or hemorrhages from the mouth and nose and into the skin If acute hepatic atrophy occurs in a pregnant woman, abortion ensues and there is profuse vaginal hemorrhage

As death approaches, there is a subsidence of the delirium and restlessness, and the drowsiness and stupor increase until final coma supervenes. Associated with the coma is a progressive rise in temperature until death

The duration of the entire course of the disease is variable Death usually occurs in from 3 to 5 weeks after the beginning of the icteric stage of the disease

EXAMINATION The characteristic observation on physical examination from time to time is the progressive decrease in the size of the liver In the more severe instances of the disease the shrinking may be so great that the hepatic percussion dullness completely disappears Ascites may be demonstrated in some patients, particularly in those who survive for longer than the average period of time (6 or more weeks) Associated with the ascites there may be edema of the lower extremities

There is a moderate decrease in the erythrocytes The concentration of bilirubin in the serum increases to as much as 30 or 40 mg per 100 ml The qualitative van den Bergh reaction is of the direct type The value for fasting blood sugar is often low The total blood cholesterol is low The cholesterol esters and urea may disappear from the blood The prothrombin time is increased, owing to the combined influences of faulty absorption of fat-soluble vitamin K from the bowel and inadequate synthesis of prothrombin by the liver False positive serologic reaction (Wassermann) may be obtained The urine is bile stained, usually contains albumin, and may show numerous casts

DIAGNOSIS The symptoms of the preicteric stage followed by intense jaundice, nervous and mental disturbances, hemorrhages, and laboratory evidence of changes in metabolic function of the liver are diagnostic In patients who have abdominal pain with the jaundice, the onset of coma indicates that the disturbance arises from more severe causes than those which produce simple mechanical jaundice

Acute yellow atrophy of the liver is generally a fatal disease. In this disease the

outcome is more predictable from the seriousness of the symptoms than by any other means

Pyogenic Abscess of the Liver. Hepatic abscesses are rare but they may occur in association with systemic pyogenic infections, in certain parasitic diseases, and in trauma, and finally there are the primary idiopathic hepatic abscesses. In the idiopathic abscesses it is impossible to demonstrate an antecedent causal focal infection or to isolate an infective organism.

Pyogenic abscess or abscesses of the liver occur oftener in young adults than in members of other age groups and affect the sexes equally.

Hepatic abscesses are commonly caused by *Escherichia coli*, the streptococcus, the staphylococcus, and varying combinations of these organisms. Anaerobic nonhemolytic streptococci have rarely been cultured from abscesses of the liver.

Hepatic abscesses in association with staphylococcal septicemia are the commonest of all In *Staphylococcus aureus* infections a latent period usually supervenes between the focal staphylococcal infection and the development of hepatic abscesses. This latent period may be of several months' duration after a carbuncle due to the *Staphylococcus aureus* has seemingly healed Very often the pus in pyogenic abscess of the liver is sterile as well as the cultures. Abscesses of the liver occur more frequently after appendical infections than in any other disease

Abscesses of the liver are single in one half of the cases Multiple abscesses occur from infections reaching the liver through pylephlebitic or hepato-arterial routes Single abscess occurs several times more frequently in the right than in the left lobe and is usually found near the dome of the liver In instances in which an abscess has been present from 1 to 2 years, granulomatous changes are often marked

Chills, fevers and sweats are common symptoms. Fever, usually of the remittent or intermittent type, is the first symptom present; the temperature ranges between 100 and 104 F (37.8 and 40 C).

The daily occurrence of chills is common in association with hepatic abscesses There is dull pain over the liver In some the pain may be situated in the axillary line, in others the pain may extend to the lateral lumbar region Anorexia, loss of weight, and weakness, dyspnea and a hacking, nonproductive cough may be present

On examination slight guarding of the rectus muscle in the upper right quadrant of the abdomen often is present. Limitation of expansion of the right lower portion of the thorax with dullness and rales at the base of the right lung is common Pleural effusion on the right side and empyema may be present in cases of single pyogenic abscess of the liver. Elevation of the diaphragm together with restriction in mobility is commonly found

In single pyogenic abscess of the liver, jaundice is not common, but in association with multiple abscesses of pylephlebitic origin it frequently is present The presence of jaundice in any case of liver abscess implies a grave prognosis.

Laboratory procedures reveal albuminuria in the presence of high fever Bile may appear in the urine when there is jaundice. Leukocytosis is commonly present. The more chronically and seriously ill patients have anemia

The procedure of aspirating pus from the abscess and injecting thorium dioxide into the abscess cavity to delineate its size, shape and position is not recommended

In those who have fever and chills and have pain and tenderness in the hepatic region with enlargement of the liver and an elevated diaphragm on roentgenologic

: abscess and amebic abscess of
be a *history of dysentery*, often
chronic and recurring. The demonstration of *Endamoeba histolytica* from the stools strongly favors the diagnosis of amebic abscess.

All of
ing

hepatic abscess The roentgenologic findings may serve to distinguish these two lesions

The prognosis of hepatic abscess is almost invariably hopeless unless surgical operation is performed Pleural and pulmonary complications adjacent to the diaphragm and subphrenic abscess are likewise conditions for surgical treatment. Operations are not advised in the presence of pyemia and abscesses in the lungs, kidneys, spleen or brain

Syphilis of the Liver. Syphilis of the liver is of either the congenital or the acquired type, depending on the mode of infection and the age at which the infection begins.

Congenital Hepatic Syphilis. In congenital syphilis the liver is increased in size and the hepatic changes tend to be diffuse. The surface is smooth The color of the liver is lighter and possesses a gray, grayish yellow, or yellowish tinge On section the organ may be firmer than is normal The cut surface may show small gray spots due to syphilomas or miliary gummas The spleen is enlarged and is much firmer than the spleen of a healthy infant Amyloid disease occurs in some of the older children.

Many children who are born alive and survive for a few weeks appear healthy The abdomen is usually prominent owing to enlargement of the liver and spleen and to tympanites

The physical findings of congenital syphilis include the cutaneous, mucosal and bony lesions together with anemia, and wasting or enlargement of the liver and spleen In some the enlarged liver may be palpated in the region of the iliac crest Ascites is common The spleen is enlarged in about half of the cases Jaundice is often present, and may be of the intermittent type Congenital hemolytic icterus has been recorded in association with congenital syphilis of the liver

The diagnosis is not difficult in the presence of the foregoing physical findings. A positive serologic reaction will be present in either the mother or the child

Delayed Congenital Syphilis of the Liver. Ten to 20 years is the average age of patients afflicted with late congenital hepatic syphilis These patients are poorly developed and often exhibit signs of infantilism The syphilitic lesions involve the liver, the sense organs and bones Amyloid disease is often present Hepatic enlargement, splenic enlargement and ascites are commonly found and may be associated with jaundice.

The foregoing findings in association with Hutchinson's teeth, deafness, interstitial keratitis, or infantilism are diagnostic. Without these findings the diagnosis of acquired syphilis is more safely made than when they are present If a tumor is palpated, the possibility of hepatic cysts or malignant disease of the liver is entertained If ascites is a prominent finding, tuberculous peritonitis, Banti's syndrome and hepatic cirrhosis are possible diagnoses

The prognosis in late congenital hepatic syphilis is grave

Hepatic Lesions During the Secondary Stage of Syphilis. The occurrence of jaundice during the secondary stage of syphilis is rare If an arsenical drug has been administered, the differentiation between syphilitic jaundice and arsenical jaundice will be impossible

A presumptive diagnosis may be made if there are the history of a recent chancre and the presence of the syphilitic exanthem At this stage of the disease the serologic reaction is usually positive, but not invariably so

Hepatic Lesions During the Tertiary Stage of Syphilis. The tertiary lesion of hepatic syphilis is the gumma, which is often associated with fibrotic changes, the result of healing O'Leary has estimated the incidence of hepatic syphilis among patients admitted to the Mayo Clinic for surgical or medical treatment, or both, as

[illegible] of hepatic syphilis in cases of tertiary
[illegible] clinical means and, in most instances,

Tuberculosis of the Liver. Hepatic tuberculosis has little clinical significance The liver commonly is involved, along with other organs of the body, in the terminal stages of miliary tuberculosis, but local tuberculosis confined to the liver is exceedingly rare.

Actinomycosis of the Liver. Hepatic actinomycosis is extremely rare. Abdominal distention, abdominal pain and tenderness, and the palpation of a mass often constitute the preliminary clinical manifestations Later the liver is enlarged and often tender, and fever is frequently present. Jaundice and ascites seldom occur but anemia and varying degrees of leukocytosis are common. The diagnosis depends on the recovery of the ray fungus from the discharging abscess of the liver, abdominal wall, pleural cavity, or other region

Diseases of the Liver Due to Infection by Higher Animal Parasites. Clonorchiasis. All known species of the superfamily Opisthorchioidea belong to the family Opisthorchiidae The species parasitic in man are *Clonorchis sinensis, Opisthorchis felineus, Opisthorchis viverrini* and *Opisthorchis noverca*

The fluke *Clonorchis sinensis*, causative agent of clonorchiasis, is a parasite of fish-eating mammals in Japan, China, Formosa, Korea and French Indo-China Man and other mammals become infected by eating raw or imperfectly cooked fish

The changes produced by *Clonorchis sinensis* are localized in the distal biliary passages, particularly of the left lobe of the liver. The injury to the host depends on the number of worms, a few parasites causing little damage, but large numbers producing serious and progressive hepatic disease The irritative action of the parasite and its toxic secretions produce an adenomatous proliferation of the biliary epithelium with thickening of the walls of the ducts and formation of crypts

Early light infections are without appreciable symptoms The characteristic early symptoms [illegible]
liver wit [illegible]
heavier [illegible]
infections these symptoms are aggravated by the involvement of the hepatic circulation, and ascites and cachexia.

The diagnosis is based on finding the characteristic ova in the feces Patients seldom die from clonorchiasis

Opisthorchiasis. *Opisthorchis felineus* is found in man only in the highly endemic areas of East Prussia and Poland, in the Ob Basin of Siberia, and in the Philippines and India.

The hepatic lesions produced by *Opisthorchis felineus* are similar to those caused by *Clonorchis sinensis*

The symptomatology in general resembles that caused by *Clonorchis sinensis.* There may be fever, chills and sweating, loss of appetite, abdominal pain, frequent yellowish watery stools, enlarged liver, slight jaundice, a polymorphonuclear leukocytosis and anemia

The diagnosis is made by finding the characteristic ova in the feces.

Fascioliasis (*Liver Rot*). The flukes are parasitic worms of the class Trematoda of the phylum Platyhelminthes

All members of the superfamily Fascioloidea belong to the family Fasciolidae. One species, *Fasciolopsis buski*, is an important intestinal parasite of man Two other species, *Fasciola hepatica* and *Fasciola gigantica*, are accidental parasites of man. *Fasciola hepatica* is the cause of liver rot

The habitat of the fluke is the biliary passages

Although the endemic center for liver rot is Cuba, the geographic distribution is cosmopolitan where sheep husbandry is practiced. In the United States of America the disease occurs along practically all the coastal streams where the pasture ground is low and thus a natural habitat for suitable species of snails

In heavy infections the migrating larvae may produce extensive destruction of the liver in animals. The pathologic processes result from the mechanical, irritative and

toxic actions of the parasites Hepatic enlargement is followed by portal cirrhosis with atrophy of the hepatic cells and portal vessels.

The symptoms are those of acute hepatic and biliary disease. There are pain on pressure over the liver, jaundice, irregular fever and persistent diarrhea. The patient may be profoundly toxemic with cachexia and anemia from the effects of hepatic damage and perhaps from the absorption of the toxic products of the living and dead worms The ingestion of raw infected liver may be followed by symptoms of suffocation resulting from the pharyngeal attachment of adult worms

Diagnosis is established by finding the ova in the feces or in material obtained by biliary drainage. The presence of ova in the feces of persons who have recently eaten infected liver may not be indicative of infection, since the ova pass undamaged through the intestinal tract

The prognosis is grave in heavy infections

Dicrocoeliasis. The species of fluke, *Dicrocoelium dendriticum*, infecting man belongs to the family Dicrocoeliidae This fluke is common in Europe and is found in northern Africa, Asia (Syria, Turkestan, Siberia and China), and in North and South America

The principal definitive host is the sheep. The intermediate hosts are the snails.

The adult worms inhabit the biliary tract. The immature worms first invade the biliary capillaries and later descend to the main ducts and gallbladder.

There may be vague digestive disturbances, for instance flatulence, chronic constipation, diarrhea and enlargement of the liver.

The diagnosis is made by finding the characteristic ova consistently present in the feces Their temporary presence may result from the ingestion of poorly cooked infected liver.

Perihepatitis. Perihepatitis exists in both acute and chronic forms

Acute Perihepatitis. Penetrating wounds and intrahepatic disease which reaches the surface of the liver result in perihepatitis Perihepatitis may have its origin in the thorax and may reach the tissues surrounding the liver by a spread through the diaphragm.

An active local congestion of the upper surface of the liver is followed by the formation of a plastic exudate which, during healing, may become absorbed or may form adhesions to adjacent structures

A constant symptom of acute perihepatitis is pain in the region of the liver which may extend to the epigastrium or to the shoulder and which is made worse by deep breathing or movements of the body The presence of a dry cough, hiccough and shoulder-tip pain is indicative of diaphragmatic irritation

On examination there may be observed limitation of motion of the right side of the thorax and guarding of the abdominal muscles in the right side of the hypochondrium. The liver may be tender In some instances a friction rub synchronous with respiration can be heard over the liver

In the presence of intra-abdominal or intrahepatic infection the occurrence of sharp pain in the hepatic region is suggestive of perihepatitis. The diagnosis of acute perihepatitis, except the gonorrheal form in women, is not made clinically.

Acute Gonococcal Perihepatitis. A woman who has a proved gonorrheal salpingitis may have an acute gonorrheal perihepatitis months or even years after having had an acute salpingitis Acute gonorrheal perihepatitis is said to be characterized by adhesions between the anterior surface of the liver and the abdominal wall

There may be a history of antecedent lower abdominal discomfort, menstrual irregularities, fever, leukorrhea, and dysuria. There is a period of quiescence of pelvic symptoms from the gonorrhea or there may have never been any pelvic symptoms from gonorrhea before the sudden onset of pain in the region of the liver. The pain is severe, beginning in the right upper abdominal quadrant, and passing through to

the scapular region or to the right shoulder tip. Nausea, vomiting, upper abdominal distention, headache, sweats, and chilly sensations and fever accompany the acute pain. The temperature rises from 99 to 103 F (37.2 to 39.4 C) with a corresponding acceleration of the pulse rate. Rapid shallow respirations may be present.

On physical examination abdominal distention may be pronounced. The liver is palpable Muscle guarding and tenderness of the abdominal wall in the right upper abdominal quadrant are constantly present. Physical signs of poor aeration of the lower lobe of the right lung are commonly obtained A transient to-and-fro friction rub may be present during the early stages of the disease. Pelvic examination, however, usually reveals evidences of active or passive inflammatory changes in the uterine tubes.

Examination of the blood reveals a moderate leukocytosis accompanied by an increase in the nonfilamented neutrophils A rapid sedimentation rate of the erythrocytes is the rule and it may persist long after the acute process has subsided. Gonococci are usually identified in the urethral and cervical smears or cultures, although failure to demonstrate the organisms does not render the diagnosis untenable. Fitz-Hugh reported the recovery of gonococci from peritoneal exudate in 1 case during the subsiding stage of the disease

Diagnosis. Positive cultures on special mediums for growth of the gonococci from vaginal smears or aspirated pus are diagnostic The evidence of pelvic inflammation followed by the forementioned symptoms and physical findings is sufficient for a presumptive diagnosis unless there are reasons which render the diagnosis untenable

The outlook is uniformly good

Chronic Perihepatitis (*Polyserositis*) Chronic inflammation of the capsule of the liver, either localized or generalized, is termed chronic perihepatitis This rare disease has also been variously designated chronic peritonitis with perihepatitis, chronic hyperplastic perihepatitis, multiple serositis, polyserositis, simple diffuse chronic peritonitis, chronic obliterative peritonitis and chronic exudative peritonitis

The etiologic agent is unknown. The disease occurs in both men and women of middle life

Chronic perihepatitis is characterized by the formation on the surface of the liver and the gallbladder of a thick layer of fibrous tissue There is often an extension from an acute inflammation, particularly the localized form. Adhesions are commonly present between the liver and contiguous structures The spleen is enlarged The omentum becomes shortened and thickened so as to produce a palpable mass in the abdomen The right pleura is more often thickened than the left. The pericardium is less frequently affected than the pleura

There are transient attacks of pain in the right upper abdominal quadrant. Progressive ascites which requires repeated paracentesis is the rule. However, a chronic ascites may accumulate and remain for years without causing a constitutional symptom or requiring paracentesis. In some, chronic renal insufficiency develops and then edema ensues. The disease may progress until all of the serous cavities are filled with fluid and there is a general anasarca

The diagnosis can be made only at operation or at necropsy. Eventually death occurs as a result of intercurrent infection or circulatory failure

Cirrhosis of the Liver. Cirrhosis of the liver is often a degeneration or an atrophy of the parenchymal cells with hypertrophy of the interstitial tissues Often it seems that inflammation progresses simultaneously with destruction of the hepatic

[illegible] gnosed,

namely, (1) portal, (2) toxic and (3) biliary.

Portal cirrhosis is the ordinary form of the disease. Laennec's cirrhosis or alcoholic cirrhosis is included in the diagnosis of portal cirrhosis In advanced portal cirrhosis there is an obstruction to the portal circulation. It is the consensus that a portal cir-

rhosis includes the end stages of toxic, infectious, nutritional, or circulatory disturbances of the liver.

It is accepted that *toxic cirrhosis* is the late result of necrotizing lesions of the liver. In toxic cirrhosis there is death of the hepatic cells and collapse and condensation of the stroma so that the liver is irregular in shape and small in size. It is almost characteristic of toxic cirrhosis not to cause symptoms, and the disease is recognized only at necropsy

Biliary cirrhosis arises from biliary obstruction The site of the inflammatory processes is around the bile ducts The severity of the lesion depends on the degree and duration of the obstruction, and the presence or the absence of infection.

Portal Cirrhosis. (*Laennec's Cirrhosis, Atrophic Cirrhosis, Alcoholic Cirrhosis, Hobnail Liver*) This is the common form of cirrhosis which frequently affects middle-aged men

In recent years data have accumulated which indicate that in cirrhosis of the liver there are disturbances of fat and carbohydrate metabolism and deficiencies of protein and certain vitamins The known importance of alcohol in the development of cirrhosis in certain patients is just beginning to be delineated by its relationship to vitamin (vitamin B) deficiencies.

[illegible] ie same person. [illegible] 7 5 per cent of [illegible] e joint etiologic agents in an additional 8 5 per cent.

Repeated injury to the hepatic cells or failure in recovery from acute injury from infection or toxic agents because of unfavorable nutritional factors may result in degenerative changes in the liver and in the development of all of the pathologic and clinical features of cirrhosis

The incidence of alcoholism among cirrhotic patients is high Some persons who consume quantities of alcohol do not eat enough good food. Over long periods they eat at very irregular intervals and in insufficient amounts, and subsequently they enjoy gross dietary overindulgences It may be that alcohol plays an important part in the development of cirrhosis of the liver because the diet of those who drink heavily often is inadequate and cirrhosis follows as a consequence of dietary deficiency, or because alcohol may induce certain metabolic disturbances of the hepatic cells which lead to excessive deposition of fat which, in turn, may cause cirrhosis. Fleming and Snell expressed the opinion that portal cirrhosis was alcoholic in origin in 42 5 per cent of their 200 cases

Bollman and Mann produced a lesion similar to that of portal cirrhosis by repeated administration of sublethal doses of carbon tetrachloride or of tetrachlorethane. Substances such as these, and the heavy metals, arsenic, lead and mercury, however, are only rarely important in the production of human cirrhosis (see Chapter 19).

Metabolic and Endocrine Disturbances The incidence of cirrhosis in *diabetes* is low, it was reported by Wilder to be only 0.7 per cent in 2,584 cases

Injury to the liver is common in *hyperthyroidism* Beaver and Pemberton found that these hepatic injuries range from acute degenerative lesions to subacute toxic atrophy and toxic cirrhosis Thyrotoxicosis is responsible for relatively few instances of cirrhosis, but it may be important as a causative factor in an individual case.

In human beings fatty livers develop in the course of starvation, diabetes and alcoholism Cirrhosis may result from certain specific deficiencies also which either favor deposition of fat in the liver or deprive the hepatic cells of elements needed for their internal metabolism These deficiencies seem to have a constant relationship to vitamin B deficiencies

Prolonged and severe congestion of the liver is a factor in the production of the hepatic disturbances Chronic passive congestion of the liver often occurs in association with congestive heart failure In these cardiac patients there are ascites, jaundice and splenomegaly.

THE CIRRHOTIC PROCESS The cirrhotic process produces alterations in the vascular relationships within the lobule Destruction of the parenchyma and contraction of the fibrous tissue bring the central veins closer to the portal spaces.

The studies by McIndoe of corrosion specimens of cirrhotic livers showed that there is great diminution of the total vascular bed The main portal trunks are attenuated and stenosed and the smaller portal vessels are distorted and twisted. There is an almost total loss of normal relationship between the portal and the hepatic arterial circulations In perfusion experiments McIndoe was able to show that from 86 to 100 per cent of fluid introduced into the portal vein passed into collateral channels rather than into the hepatic vein. The hepatic tissue had become almost entirely dependent on the hepatic artery for nutrition.

The forcing of the portal blood into other channels is responsible for the development of collateral circulation and often results in hemorrhage, for example, from esophageal varices The body is deprived of the metabolic and detoxifying functions of the liver since blood from the gastrointestinal tract is shunted into the general circulation without coming in contact with the hepatic cells. The regenerative ability of the liver is markedly reduced when portal blood is prevented from reaching the organ

The capsule of the liver is thickened, and the surface is uneven and studded with nodules, uniform in size and distribution. The variations in size of the nodules and the contraction of the fibrous tissues between them cause the liver to be extremely irregular in contour

Cirrhosis is essentially a disease of late middle life. The disease occurs at a somewhat earlier age in women than in men. It may occur in children The higher incidence of alcoholism in men is ordinarily given as the explanation for a higher occurrence of cirrhosis among them than among women

Environmental rather than constitutional factors determine the differences in race incidence The disease occurs in all races under comparable environments

SYMPTOMS. Snell reviewed the early symptoms in 112 cases in which ascites had already developed He listed the early symptoms as anorexia, flatulent indigestion, jaundice, abdominal pain, asthenia, diarrhea, hematemesis, vomiting, edema, enlarged liver or spleen, and pruritus Ascites had developed suddenly and without warning in 18 per cent of these cases

Anorexia may be profound and lead to marked loss in weight The digestive disturbances may result from the effect of cirrhosis on the secretory and absorptive functions of the gastrointestinal tract Flatulent indigestion consisting of belching of sour material is commonly associated with anorexia.

Abdominal pain occurs in 1 of every 3 cases of portal cirrhosis It is usually localized to the right upper quadrant or to the epigastrium but may be generalized No obvious explanation can be found The pain may be associated with jaundice, weakness and diarrhea.

Hemorrhagic phenomena, such as epistaxis, occur with fair frequency in cirrhosis. These may be the result of hypoprothrombinemia in some instances and thrombocytopenia in others It is more probable, however, that localized vascular disturbances are the principal cause of the hemorrhages Grave hematemesis may be associated with esophageal varices.

Cerebral disturbances, comprising the loss of concentrating ability, confusion, restlessness, depression, delirium and actual psychoses, may occur

Fever occurs in cirrhosis in the absence of inflammatory processes After persisting for a long period, the fever may disappear spontaneously only to recur later in the course of the disease

EXAMINATION. On examination may be found a type of vascular cutaneous change, the *spider nevus*, that is characterized by a central point from which radiate fine branches for a distance of about 1 cm. Patek found that these nevi either consist of an artery and its arteriolar branches or resemble an arteriovenous anastomosis (glomus). Nevi occur over the sternum, the upper part of the thorax, the *shoulders*, and occasionally on the lower part of the trunk and on the legs.

Often there is a superficial vascular change in the palms of the *hands (palmar erythema)* (see Hands, Chapter 6). This palmar erythema is manifested by flushing

of the thenar and hypothenar eminences and is observed in active cirrhosis and in nutritional deficiency, regional enteritis and chronic ulcerative colitis. It seems to be associated with decreased concentrations of serum albumin.

Pruritus is fairly common in cirrhosis, and may be independent of the occurrence of jaundice

Collateral Circulation The locations for collateral circulation in portal obstruction in the gastrointestinal tract are (1) at the cardiac end of the stomach and at the anus, (2) at the site of an obliterated embryologic circulation, through the falciform ligament and para-umbilical veins and, rarely, through remnants of the umbilical vein The collateral circulation through these channels is responsible for the formation of the distended veins which may often be found on the abdominal wall of a patient who has cirrhosis. Collateral circulation occurs (3) at situations where the gastrointestinal tract, or its glands or appendages, becomes adherent to the abdominal wall, developmentally or pathologically

In the course of physical examination it may be observed in some that the collateral circulation between the portal system and the superior and inferior caval systems has produced visible distention of these veins on the anterior abdominal wall and, in rare instances, may result in the formation of the caput medusae (cirsomphalos), a cluster of dilated veins around the umbilicus with the direction of blood flow away from the umbilicus

Distended veins which connect the portal system with either the superior or the inferior vena cava usually occupy the midportions of the abdominal wall, and this situation of the veins serves somewhat to distinguish them from the collateral circulation which forms when the caval system is obstructed In obstruction to the portal circulation the blood distending the veins flows upward in the veins of the upper one third of the abdomen and downward in the veins of the lower two thirds.

Slight icterus is present in one half of those who have cirrhosis. The jaundice may appear at any time in the course of cirrhosis, but it is rarely prominent in the early findings It is common for a hyperbilirubinemia to persist once it has begun

The liver is often enlarged, and it remains about the same size during the entire period of observation

It may be difficult to palpate the spleen in an abdomen distended by fluid or gas Splenic enlargement is commonly found late in the disease in association with ascites It may be found early in the course of cirrhosis and may be present for a long period before other definite evidence of the disease appears The spleen may fluctuate in size considerably and decrease after a hemorrhage

Ascites is present in more than one half of those who have a cirrhosis of the liver Edema of the lower extremities is present in 1 of every 3 who have an advanced cirrhosis of the liver The reason for the edema is the hypoalbuminemia caused by the cirrhosis Hydrothorax may be present and it may be unilateral or bilateral

Peripheral neuritis, paraplegia, absence of deep reflexes, hyperalgesia of the muscles and nerve trunks of the legs, and drop foot may be present in those who have cirrhosis of the liver and chronic alcoholism

Anemia is observed commonly in patients who have cirrhosis The anemia is a natural consequence and is due to malnutrition, bleeding and hepatic injury

The anemia of cirrhosis is often of the macrocytic variety and moderate in degree The erythrocytes are uniform in size with little or no anisocytosis or poikilocytosis

The leukocyte count varies considerably in the course of cirrhosis. Leukopenia is fairly common

The concentration of serum bilirubin is increased in a great many cases of cirrhosis, not only in those in which clinical jaundice is present but also in many in which there is no indication of jaundice. The degree of bilirubinemia is ordinarily not excessive.

There is a decrease in the excretion of sulfobromophthalein, when employed as a test of liver function, in a patient who has cirrhosis of the liver.

A decrease in the concentration of serum albumin is commonly observed in cirrhotic patients, particularly if ascites is present. The decrease in concentration of serum albumin is probably a specific result of hepatic dysfunction. Many patients who have an advanced cirrhosis have increased concentration of the serum globulin, with inversion of the albumin-globulin ratio.

The urine is usually decreased in amount and of a high specific gravity. It contains increased amounts of urobilinogen and may contain bilirubin if the patient has jaundice

Biopsy in Cirrhosis of the Liver. The correlation between clinical and laboratory observation and the histologic features as revealed by bits of liver obtained for biopsy indicate that the evidence of diffuse damage to hepatic cells is more closely identified with objective clinical and laboratory observations than with coagulation necrosis, infiltration with fat, focal necrosis or leukocytic reactions. This suggests that injury to hepatic cells is the most important factor in determining the clinical activity in cirrhosis Hepatic tests performed within 2 to 7 days of the biopsy reveal that the cephalin flocculation and thymol turbidity tests appear best to indicate the presence of diffuse injury to hepatic cells in cirrhosis In the presence of cell injury in cirrhosis there is a serum-albumin reduction and to a lesser degree a serum-globulin elevation and reduction of albumin-globulin ratio Patients who have an alcoholic history reveal, in general, less damage to hepatic cells and more infiltration with fat than those without such a history Ascites coincides most with scarring and other phenomena associated with fibroplasia and inflammation in the portal triads and in the connective tissue trabeculae. The type of cirrhosis associated with jaundice does not reveal specific morphologic characteristics except for the presence of static bile pigment.

Contraindications to Needle Biopsy of the Liver Attempts to needle a small liver are dangerous because of the ease with which a loop of bowel can be perforated Kleitsch and Kehne never do needle biopsies if the edge of the liver cannot be definitely palpated. A prolongation of the clotting or bleeding time should contraindicate this procedure. In some cases it may be possible to lessen the bleeding time of the patient by the administration of vitamin K, but should the hemorrhagic diathesis persist, biopsy should not be attempted Another important contraindication is obstructive jaundice, the reason being that dilatation of the peripheral biliary radicles will make perforation of one of them by the aspirating needle likely When one of these dilated biliary radicles is perforated, there is a tendency to establishment of a biliary fistula which, in turn, will produce a bile peritonitis The authors described such an experience which followed needle biopsy of a patient in whom jaundice was due to carcinoma of the head of the pancreas.

DIAGNOSIS The diagnosis of cirrhosis of the liver in its early stages is difficult and uncertain Liver biops
less or causes symptoms
disturbance The presence
man who has grade 2 (c
when administered as a test of liver function, is sufficient for a diagnosis This test is inaccurate in the presence of jaundice When jaundice exists, some such procedure as the thymol turbidity test should be employed The combined information given by the sulfobromophthalein, urobilinogen, hippuric acid and cephalin-cholesterol flocculation tests and the determination of the serum-albumin content is much greater than that given by any one of these tests alone

The diagnosis of fully manifested cirrhosis when there are ascites, hematemesis, persistent low-grade jaundice, splenomegaly, and visible collateral venous channels is not difficult.

the disease is usually fairly rapid

In portal cirrhosis acute [illegible] pneumonia, erysipelas, and non-

tuberculous peritonitis, are frequent. Tuberculosis is frequently a terminal event Hernias are relatively common in patients who have cirrhosis, particularly in those who have ascites

Of patients who die directly of cirrhosis, approximately one third die of hemorrhage and two thirds die of progressive failure of the liver The terminal event is often called cholemia, of which coma is the characteristic feature.
